Tests based on sperm–zona pellucida binding cannot be applied to certain species for a variety of reasons, including limited access to females or oocytes. Alternative approaches such as in vitro fertilization assays using heterologous oocytes have been explored. In some cases, the oocyte's zona pellucida, important for species-specific gamete recognition, has to be removed to allow for fertilization, as in the so-called “sperm penetration assay” (SPA) for human sperm in which zona-free golden hamster oocytes are employed (Oehninger et al., 2014). The SPA measures the sperm ability to undergo capacitation, spontaneous acrosome reaction, fusion and penetration through the oolemma, and decondensation within the cytoplasm of hamster oocytes. This was one of the first functional tests to be introduced to evaluate male fertility potential but results have been difficult to interpret among other reasons because of rather high rate of false-negative results (men whose spermatozoa fail the SPA but successfully fertilize human oocytes in vitro or in vivo). A pair or meta-analysis revealed poor clinical value of the SPA as predictor of fertilization (Oehninger et al., 2014).

Heterologous sperm–oocyte interaction assays have been used in other species. A test resembling the human SPA has been used with domestic ungulates but it has not gained general acceptance. In felines, an heterologous test to assess fertilization is used but in this case, removal of the zona pellucida is not required. Domestic cat oocytes matured in vitro can be fertilized by a variety of feline species, thus serving as a useful test of sperm fertilization potential, particularly for endangered species (Roldan and Gomendio, 2009).

Towards New (and More Inclusive) Assays of Male Fertility

For many years now, the use of ICSI has become widespread for cases of male factor infertility and for couples who have failed conventional IVF. The high levels of fertilization achieved with ICSI, even in cases of multiple morphological and dysfunctional sperm defects, as well as the possibility of using testicular or epididymal spermatozoa, or cryopreserved spermatozoa, may have diverted attention from the need to identify causes of male infertility. There are thus many unanswered questions regarding sperm pathologies and the underlying molecular and cellular causes, or the role of sperm components in early development or postnatal development, with important implications for future reproductive performance, or wellbeing in general, in the offspring. Thus, the need to understand the many bases of male infertility is a priority. Furthermore, in order to have reliable evaluations of male fertility in general, or sperm function, better tests should be designed and implemented.

One overall priority in the area of male fertility is a better understanding of processes of production, formation, maturation and structure-function of spermatozoa. There is a crucial requirement to investigate the different genetic and phenotypic aspects of sperm biology, and obtain a much better grasp of molecular, biochemical, cellular and physiological mechanisms, with a view to design more reliable diagnostic and prognostic assays, consider more appropriate therapies and evaluate the impacts of lifestyles, age and environmental factors on these processes (Barratt et al., 2017). Despite much progress in recent years, there is still the need to make significant progress in certain areas, including taking into consideration new technological breakthroughs in other areas, and, perhaps, even rethink some of the strategies for diagnosis and treatment.

There seem to be two divergent trends nowadays that may determine the future of semen analyses and male fertility assessments. On the one hand, options for in-home evaluation of semen quality are becoming commercially available, and thus accessible and affordable kits may become the first line of action for a quick evaluation of one or more basic parameters, such as sperm numbers or sperm motility. Currently, there is much interest in the development of devices and software to be used in conjunction with smart-phones. Although this may appear at first as a drawback for the andrology laboratory it may in fact represent a considerable gain allowing more men to approach testing in a less stressful way. Beyond the use of kits in human fertility testing, these devices may

also become useful in other situations such as the quick assessment of semen quality in farms in which frozen or refrigerated semen is used in artificial insemination.

On the other hand, there is room for much improvement in research and clinical laboratory tests that would allow more exhaustive assessments of sperm function. There is an urgent need for the development and use of assays that go beyond basic semen parameters (such as sperm concentration, morphology and motility) and that can yield multiparametric dynamic evaluations of changes taking place in spermatozoa under conditions that mimic preparation for fertilization, or that would ensure long-term survival of the genetic resource. In this regard, development of assays that evaluate sperm metabolism, capacitation, acrosome reaction, swimming velocity and trajectory, sperm DNA integrity, chromatin compaction, or various protein changes including protamine ratios deserve attention. Consideration of the arena in which spermatozoa perform would also be important and, therefore, the development of chips for assessments through microfluidic devices should be considered. These devices will be most useful for the evaluation of spermatozoa, for sperm cryopreservation or in the selection of competent sperm for fertilization.

Fertility, Sperm Number and Motility

Introduction

Semen has two major quantifiable components: sperm cells and seminal fluid. The nature of the spermatozoa, motility, vitality and morphology, and the composition of seminal fluid are important for sperm function. Thus, evaluation of male fertility has traditionally relied on the analysis of spermatozoa, notably sperm count and motility.

This analysis has been carried out since the beginning of the 20th century and more particularly since the 1970s. In response to a growing need for the standardization of procedures for the examination of human semen, the first WHO laboratory manual for the Examination and processing of human semen has been published in 1980.

Numerous publications have been produced in an attempt to find a link between sperm parameters and the patient's fertility status. At this time, semen analysis is used as a marker of male fecundity in clinical andrology and is examined routinely in ART (Assisted Reproductive Technology) laboratory. It is considered an important component of the evaluation of couples presenting for fertility evaluation. Semen analysis is also performed in reproductive toxicology, epidemiology, and risk assessment in order to better understand the causes of variation in sperm quality.

Sperm Number and Motility: Methods and Limits

The routine evaluation of human semen including sperm count and motility is subjective by nature. All aspects of semen collection and analysis must be done by properly standardized procedures if the results are to provide valid, useful information. The WHO manual for the examination of human semen proposes a standard methodology for laboratories for several decades. In each given subject the characteristics of semen can be influenced by the conditions of sample collection, the length of abstinence, and any disease that may have occurred in the 3 months preceding the examination.

The semen samples are obtained by masturbation and ejaculated into a clean collection tube. WHO recommends that semen samples should be collected after a minimum of 48 h but not more than 7 days of ejaculation abstinence to standardize the influence this factor ([World Health Organization, 2010](#)). Ejaculate volume is estimated by weighing the collection tube with the semen sample and subsequently subtracting the predetermined weight of the empty tube, and assuming that 1 mL of ejaculate weighs 1 g. Phase-contrast microscopy is used for the examination of semen.

The number of spermatozoa in the ejaculate is calculated from the concentration of spermatozoa. The sperm concentration is assessed using the improved Neubauer hemocytometer. Briefly, each semen sample is thoroughly homogenized. An aliquot of the sample is put into the diluent (NaHCO₃, formaldehyde and distilled water) and mixed. One drop of the diluted specimen is transferred to each chamber of the hemocytometer, which are allowed to stand in a humid chamber before the cells were counted at a total microscope magnification of $\times 400$ ([WHO, 2010](#)). Only spermatozoa with tails are counted, and at least 200. A comparing replicate count is required to see if they are acceptably close. If so, calculations could be proceeded; if not, a new dilution should be prepared. Sperm concentration could be calculated according to the number of spermatozoa counted in n rows, and the factor of dilution, and the total number of spermatozoa per ejaculate could be obtained by multiplying the sperm concentration by the volume of the whole ejaculate. If no spermatozoa are observed in the ejaculate, azoospermia can be suspected. A centrifugation of the whole ejaculate is required to determine if any spermatozoa are present, and the term azoospermia can only be used if no spermatozoa are found in the sediment of a centrifuged sample. If there are spermatozoa, we will use the term cryptozoospermia. Azoospermia needs to be confirmed through another analysis 3 months after.

For the assessment of sperm motility, 10 μ L of well-mixed semen is placed on a clean glass slide (which had been kept at 37°C), and covered with a 22 mm $\times$ 22 mm coverslip. The preparation is placed on the heating stage of a microscope (37°C), and immediately examined at a total magnification of $\times 200$ or $\times 400$. In the previous edition ([WHO, 1999](#)), the progressively motile spermatozoa should be categorized as rapid (a) or slow (b), and after (c) for the nonprogressive motility and (d) for immotile spermatozoa. However, it is clear that it is difficult for technicians to define the forward progression so accurately without bias ([WHO, 2010](#)). Therefore, the motility of each spermatozoon is now classified as follows: either motile, with progressive motility (PR) and nonprogressive motility (NP) or immotile (IM) ([WHO, 2010](#)) and reported as a percentage ([Fig. 1](#)). A replicate is systematically performed. Two hundred spermatozoa should be assessed per replicate. If the replicate values are acceptably close, calculations could be done; if not, it is necessary to prepare new samples.

The computer-aided sperm analysis (CASA) system was developed in the late 1980s for analyzing sperm movement characteristics. It has been successful in the field of research and for measuring semen characteristics such as sperm concentration and motility in many animal species. The use of CASA for human semen analysis has met with poor success probably due to some difficulties presented by many human semen samples, aggregation/agglutination of spermatozoa, and others cells and debris ([Mortimer et al., 2015](#)). However, the use of fluorescent DNA stains and tail-detection algorithms, may allow sperm concentration and progressive motile spermatozoa to be determined more accurately ([Mortimer et al., 2015](#)). In the same way as subjective analysis, quality control procedures will be necessary.

Fig. 1 Sperm trajectories in a microscopic field in the same time: PR, progressive motility, NP, nonprogressive motility and IM, immotile (WHO, 2010) and (a) rapid progressive, (b) slow progressive, and (c) nonprogressive and (d) for immotile (WHO, 1999).

Based on the subjective sperm count and motility assessment, quality control procedures are necessary to establish and maintain a high standard. Large discrepancies in sperm count and motility have been observed in different laboratories. Indeed, the coefficients of variation for sperm concentration can vary from 23% to 60%, and for motility from 20% to 30% (Auger et al., 2000). Many authors indicate interestingly that training and subsequent follow-up workshops can guarantee minimum variability in assessments of sperm concentration and motility among centers. Thus it is both necessary to standardize the analysis of these parameters, and to implement quality control (QC) to detect and correct systematic errors and high variability of results. Internal quality control (IQC) is essential to maintain accuracy, precision and competence in a laboratory. External quality control (EQC) is the evaluation of results for the same samples in several laboratories and is required to ensure that different laboratories produce comparable results. IQC and EQC should be performed in all laboratories and during all studies on semen quality.

The characteristics of semen can be influenced by several factors as the length of sexual abstinence and a disease and/or a fever that may have occurred in the 3 months preceding the analysis. There is general agreement that semen volume, sperm concentration and therefore total sperm count increase with prolonged sexual abstinence but the issue of sperm motility remains contradictory (WHO, 2010). The decrease of sperm motility with an increase of sexual abstinence might be due to the variation in epididymal and accessory sex gland secretions as well as the morphology of spermatozoa with an increased percentage of tail defects (WHO, 2010). Other factors such as a recent acute febrile episode may temporarily alter sperm parameters. Thus, a decrease in total sperm count but also in motility can be observed (WHO, 2010). These variable, and largely uncontrollable, factors explain the well-known intra-individual variation in semen composition (WHO, 2010).

It is therefore necessary to have information on possible exposure factors in the 3 months prior to the sperm analysis but also on the medical record and lifestyle for a better interpretation.

Thus, for a given man, spermatoc parameters can vary with time (Fig. 2). It would be misleading to draw hasty conclusions from one single analysis and a second examination is advised.

Reference Values

Until 1999, the WHO manual proposed reference values for semen parameters that had limitations. Indeed, the used data were derived from imprecisely defined reference populations, obtained from laboratories with unknown comparability with respect to analytical methodologies, and were limited by the lack of available data on semen variables in recent fathers. Moreover, there had been no consensus around the relevance of these values. A sperm concentration of $20 \times 10^6 \text{ mL}^{-1}$, the "normal" or "reference" value cited by WHO (1999), has been considered too low for a lower reference limit because the probability of pregnancy is essentially linear with sperm concentrations up to $40\text{--}50 \times 10^6 \text{ mL}^{-1}$ (Bonde et al., 1998; Slama et al., 2002). Conversely, sperm concentrations above this value are repeatedly observed in infertile patients.

In 2010, Cooper and collaborators provided reference values from a population of men, partners of pregnant women with a time to pregnancy (TTP) ≤ 12 months. Data from 1953 semen samples from five studies in eight countries on three continents were combined and analyzed. The samples were obtained and processed for analysis using adequately standardized methods under quality control.

A reference distribution for semen parameters was generated and the 95% confidence intervals for a range of semen variables and the lower (2.5th centile and 5th centile) reference limits, have been obtained, in line with clinical chemistry standards (Table 1).

Fig. 2 Variation in total number of spermatozoa and sperm concentration over a one-and-a-half-year period From World Health Organization (2010). WHO laboratory manual for the examination and processing of human semen, 5th edn. Geneva, Switzerland: WHO Press.

Table 1 Distribution of values, lower reference limits and their 95% CI* for sperm number and motility from fertile men whose partners had a time-to- pregnancy of 12 months or less

	<i>N</i>	<i>Centiles</i>								
		2.5	5	10	25	50	75	90	95	97.5
Semen volume (mL)	1941	1.2	1.5	2	2.7	3.7	4.8	6	6.8	7.6
			(1.4–1.7)*							
Sperm concentration (10^6 mL^{-1})	1859	9	15	22	41	73	116	169	213	259
			(12–16)*							
Total number ($10^6/\text{ejaculate}$)	1859	23	39	69	142	255	422	647	802	928
			(33–46)*							
Total motility (PR + NP, %)	1781	34	40	45	53	61	69	75	78	81
			(38–42)*							
Progressive motility (PR, %)	1780	28	32	39	47	55	62	69	72	75
			(31–34)*							

From Cooper, T.G., Noonan, E., von Eckardstein, S., Auger, J., Baker, H.W., *et al.* (2010). World Health Organization reference values for human semen characteristics. *Human Reproduction Update* **16**, 231–245.

WHO (2010) proposed a nomenclature with the aim to classify the quality of the semen without suggesting any biological cause. These terms are used to describe samples with values lying outside the reference range (Table 2).

Are Sperm Count and Motility Good Indicators for the Evaluation of Fertility?

For many years, the influence of semen parameters on the probability of conception or pregnancy has been studied in various situations and populations: in a fertile population, in an insemination program or couples attending an IVF/ICSI.

Table 2 Nomenclature related to semen quality (WHO, 2010)

<i>Aspermia</i>	<i>No semen (no or retrograde ejaculation)</i>
Normozoospermia	Total number (or concentration) of spermatozoa, and percentages of PR and morphologically normal spermatozoa, equal to or above the lower reference limits
Oligozoospermia	Total number (or concentration) of spermatozoa below the lower reference limit
Azoospermia	No spermatozoa in the ejaculate
Cryptozoospermia	Spermatozoa absent from fresh preparations but observed in a centrifuged pellet
Asthenozoospermia	Percentage of PR spermatozoa below the lower reference limit
Oligoasthenozoospermia	Total number (or concentration) of spermatozoa, and percentage of PR spermatozoa, below the lower reference limits
Necrozoospermia	Low percentage of alive, and high percentage of immotile, spermatozoa in the ejaculate

PR: progressively motile.

In 430 couples with men aged 20–35 who had no children (first pregnancy planners), [Bonde et al. \(1998\)](#) found that the probability of conception increased with increasing sperm concentration up to $40 \times 10^6 \text{ mL}^{-1}$. A prospective study with 210 reproductive-age healthy couples has shown an association between total sperm count, sperm concentration on the one hand, and time to pregnancy on the other ([Zinaman et al., 2000](#)). Thus, a decline in pregnancy rate was observed below approximately $30 \times 10^6 \text{ sperm mL}^{-1}$ and $80 \times 10^6 \text{ sperm}$, for sperm concentration and total sperm count, respectively. Another study also revealed for 942 partners of pregnant women that an increasing sperm concentration may influence the time to pregnancy (TTP) up to $55 \times 10^6 \text{ mL}^{-1}$ and a total sperm count up to 145×10^6 ([Slama et al., 2002](#)).

In these different studies no convincing relationships were observed between motility and pregnancy or TTP. This is probably due to the subjective analysis of this parameter and therefore to the existence of too large inter-individual variability.

Numerous studies have been carried out to investigate the value of sperm parameters to predict a pregnancy outcome in couples attending an insemination program. [Lemmens et al. \(2016\)](#) did not find a correlation between sperm count or motility and pregnancy in a fresh sample. In the same way, a recent review did not reveal a clear evident relationship between sperm quality and IUI success ([Ombelet et al., 2014](#)). However, the total motile spermatozoa (TMS) count obtained and calculated after centrifugation of a semen sample in a discontinuous density gradient column could be a good prognostic factor for pregnancy. In a recent meta-analysis, the literature did not reveal evidence on the relationship between sperm quality and IUI success probably due to a lack of prospective studies, a lack of standardization in semen analysis, an heterogeneity of patient groups and IUI treatment strategies ([Ombelet et al., 2014](#)) and authors recommended that more standardized prospective studies are needed.

In the present time, no evident correlation has been found between sperm parameters and success rates in IVF/ICSI program.

In conclusion, apart from the fertile population, sperm count and motility do not seem to be the best indicators for IUI/IVF/ICSI program. Further standardized studies should be carried out.

Factors Influencing Sperm Count and Motility

The etiology of sperm defects remains idiopathic in 30%–50% of cases. Male infertility is probably a multifactorial disorder. Indeed, different causes may be involved such as genetic, environmental, drugs, lifestyle ...factors.

Genetic factors

Azoospermia/severe oligozoospermia

Microdeletions of the Y chromosome, Klinefelter syndrome (47,XXY), and CFTR mutations are well known genetic causes of severe male infertility as azoospermia or severe oligozoospermia. Testicular causes include also germ cell aplasia (Sertoli cell-only syndrome, SCOS) or spermatogenesis arrest. The recent literature on the genetics of azoospermia and oligozoospermia has been shown that other genetic defects (X-chromosome or autosomal mutations) may have a direct quantitative effect on sperm production ([Table 3](#)).

Asthenozoospermia

Recent data allow to establish that some genes encoding for proteins involved in the assembly and/or structure of the flagellum (DNAH1, SEPTIN12) and affecting the flagella morphology or for ion channels located at the sperm plasma membrane and required for sperm motility (CATSPER, SLC26A8) are implicated in the physiopathology of isolated asthenozoospermia ([Table 3](#)).

Others factors

Western lifestyle (sedentary work/lifestyle) as well as other lifestyle factors (stress, smoking, maternal smoking, alcohol, heat...) could potentially be damaging to sperm production and quality. Endocrine disruptors including pesticide and plasticizers may also be important damaging factors. Thus, numerous epidemiological studies have been carried out from different populations to better understand the effects of lifestyle factors, endocrine disruptors on sperm production and quality. In most cases, humans studies have considered separately perinatal exposures, exposures during infancy and postpubertal to adulthood exposures.

Table 3 Genes involved in azoospermia /oligozoospermia/asthenozoospermia (Mitchell et al., 2017; Ray et al., 2017)

<i>Gene</i>	<i>Chromosome</i>	<i>Human phenotype</i>
TEX 11	X	Azoospermia
TAF4B	18	Azoospermia/oligozoospermia
ZMYND15	17	Azoospermia
SYCE1	10	Azoospermia
TEX15	8	Azoospermia/oligozoospermia
NPAS2	2	Azoospermia
SYCP3	12	Azoospermia
KLHL10	17	Oligozoospermia
SEPT 12	16	Asthenozoospermia
DNAH1	3	Asthenozoospermia
CATSPER1	11	Asthenozoospermia
CATSPER2	15	Asthenozoospermia
SLC26A8	6	Asthenozoospermia

Environmental factors

During the past decades, a temporal decline and geographical variations in semen quality has been observed. Rapidly, environmental factors and particularly, endocrine disruptors have been suspected of interfering with the sperm production and quality. Actually, the available data on the effects of environmental chemicals, such as pesticides, DDT, PCBs, or plasticizers, both in the perinatal period and in adult, on sperm quality do not permit any definitive conclusions (Skakkebaek et al., 2016). However, reports on reduced sperm counts and azoospermia in men exposed to dibromochloropropane (DBCP) and dioxin provide the proof of principle that exogenous chemicals during adult life can disturb human spermatogenesis as it has been shown in numerous rodent studies (Skakkebaek et al., 2016).

Heat

Exposure to hot occupational environment (bakers, welders, foundry workers), sedentary work habits, traveling by car for long time during commute to and from work, tight clothing, sauna, all these can disrupt regulation of intra-scrotal temperature and can lead to an increase in testicular temperature. Male heat exposure could have a deleterious effect on sperm characteristics (such as motility and morphology) as has been reported in animal models (Mieusset and Bujan, 1995) while others studies do not reach the same conclusion. Recently, it has been shown that the deleterious effects on semen quality may be reversible sometime after a cessation of heat exposure.

Alcohol/tobacco

Alcohol does not appear to have any obvious effects on sperm parameters whatever exposure period: in utero or during adulthood (Skakkebaek et al., 2016). The results of studies concerning the possible effects of adult smoking on semen quality are contrasted.

Therapeutic treatment

It is now clearly documented that treatment of cancer with chemo- or radiotherapy causes reduction of sperm counts often to azoospermic levels that may persist for several years or be permanent. Concerning the others drugs likely to affect semen parameters, a recent review showed that the levels of scientific evidence are still insufficient (at the exception of Sirolimus, Sulfasalazine, exogenous testosterone, Finasteride and Cyproterone acetate, for which the levels of evidence are higher) (Semet et al., 2017).

Psychological stress

Several studies have investigated associations between semen quality and stress due to different types of stressors: environmental disasters, occupational stress, stressful life events, stress due to infertility, etc.... Overall, these studies may reveal that semen quality including sperm count and sperm motility is impaired by different stresses. But study populations were mostly small and selected (infertile, students, healthy men, donors...). Moreover, numerous confounding factors (age, abstinence time, smoking...) were not taken into account. Lastly, there are different tools to assess stress, making difficult a comparison between studies. Psychological stress might be a modifiable or reversible factor of spermatogenesis. But, it remains controversial.

Thus, many environmental factors alone or associated can probably have effects on sperm parameters. At present, data remain controversial. However, it has been shown that in a special context such as the Seveso accident, dioxin may have a detrimental effect on sperm production confirming the adverse effects of these molecules on spermatogenesis. Futures studies are therefore still needed.

In conclusion, sperm concentration and motility are two parameters of semen analysis, and have an important role in male fertility. These analyzes are still subjective and require standardized methods but also quality control. Semen analysis is performed in the ART laboratory but also in the context of epidemiological studies. Recently, Cooper and collaborators provided reference

values from a population of fertile men and a reference distribution for semen parameters was generated. Sperm count and motility can be altered with consequences for the fertility. These causes are probably due to different factors such as genetic, environmental... but the cause can also be multifactorial.

Autonomic Nervous System and Male Reproduction

Janet R Keast and Peregrine B Osborne, University of Melbourne, VIC, Australia

Overview

The autonomic nervous system is essential for regulating the activities of male reproductive organs. It is required to orchestrate basic functions such as erection, emission and ejaculation that depend upon the precise coordinated control of smooth muscle activity, blood control and exocrine gland secretion. In addition, recent advances suggest the autonomic nervous system also regulates the immune system, tissue growth and other important functions of the reproductive organs.

The patterns of autonomic nerve activity determine the onset, intensity, duration and coordination of many reproductive organ functions. For example, propulsion of sperm and seminal fluid requires appropriately timed activation of sympathetic nerves to contract smooth muscle of the ejaculatory duct. By contrast, erection of the penis in response to mechano-sensory stimulation depends on activation of a different population of nerves—parasympathetic nerves—whereas the following period of detumescence requires the central nervous system (brain and spinal cord) to coordinate cessation of parasympathetic activity with initiation of sympathetic activity. To make these types of decisions, the central nervous system integrates sensory information from within the organs themselves (interoception) with sensory information relating to the external environment (exteroception, e.g. visual and olfactory cues). Brain and spinal circuits determine what type of response, if any, is necessary and then initiate a motor response to match the needs of the body or complete the behavior.

This chapter will first introduce general principles of autonomic regulation followed by more detailed discussion of how neural activity affects different reproductive organs, the impact of sex hormones on this neural communication and relevance to several clinical conditions.

Autonomic Regulation of Organs and Tissues: General Principles

What Is an Autonomic Axon?

Autonomic axons are present in almost every tissue of the body. They are sometimes referred to as *visceral motor axons* because their activity directly affects the organs rather than the brain. This term serves to distinguish them from *somatic motor axons* that supply skeletal muscle, bones, joints and skin. However, an important limitation of this definition of ‘visceral motor’ should be noted as some targets of autonomic nerves are found integrated within somatic tissues—blood vessels and sweat glands, for example. An alternate definition of the autonomic nervous system is the ‘involuntary motor system’ that focuses on the context and types of actions that occur when autonomic nerves are excited or inhibited. Irrespective of which definition is used, it is important to realize that “motor” means much more than causing movement—as it can refer to any change in the activity of a tissue or organ caused by the autonomic nerve. On this basis, motor events include cellular activities such as contraction or relaxation of smooth muscle, altered ion fluxes across epithelia (to stimulate absorption or secretion), glandular secretions (mucous or hormones), metabolic changes (e.g., lipolysis), cell proliferation, and modulation of immune cell function.

Divisions of the Autonomic Nervous System: Anatomical Criteria

Conventionally, the autonomic nervous system is classified into two divisions that have quite distinct anatomical and physiological features—the sympathetic and parasympathetic nervous systems (Jänig, 2008). These are the focus of this chapter. A third division is the enteric nervous system that comprises only the neuronal circuits embedded within the digestive tract (Furness, 2012). The enteric circuits have several features that are quite different from the sympathetic and parasympathetic systems, most notably having their own sensory neurons and the capacity to operate independently of the central nervous system.

A typical autonomic pathway (Fig. 1) from the central nervous system to a peripheral organ has two linked nodes. The first component is called a preganglionic neuron. This has a cell body (soma) located in the central nervous system (brainstem or spinal cord) and an axon that projects outside of the central nervous system via a ventral spinal root or cranial nerve. This preganglionic axon projects via peripheral nerves and terminates at synapses on one or more neurons that are aggregated into autonomic ganglia. Some autonomic ganglia consist of thousands of neurons but others can be very small (only tens of neurons). Autonomic ganglion neurons are the second component of the motor pathway and their axons are called postganglionic axons. Postganglionic axons project out of the autonomic ganglia and synapse with specific tissues within the organs, at neuroeffector junctions.

The sympathetic and parasympathetic nervous systems are most clearly distinguished by their anatomical features. Preganglionic neurons of the sympathetic nervous system lie in the thoracic and lumbar regions of the spinal cord. Autonomic ganglia innervated by these neurons are called sympathetic ganglia. Conversely, parasympathetic preganglionic neurons lie in the brainstem (cranial nuclei) and sacral spinal cord, so autonomic ganglia innervated by these neurons are called parasympathetic ganglia. Most sympathetic ganglia are quite distant from the organs (i.e., their postganglionic axons are quite long), whereas most parasympathetic ganglia lie very close to or even within their target organs (i.e., very short postganglionic axons). In most parts of the body,

Fig. 1 Features of the sympathetic and parasympathetic nervous systems. These two systems are defined by their location of preganglionic neurons. Preganglionic neurons of both types receive inputs from specific areas of the brainstem. In most cases, parasympathetic ganglia lie closer to the organs, whereas sympathetic ganglia lie more distant. Communication between postganglionic axons and their target tissues (neuroeffector junctions) is mediated by acetylcholine or norepinephrine (synonym: noradrenaline), with or without various co-transmitters.

autonomic ganglion cells are clustered into separate sympathetic and parasympathetic ganglia, but as we will discuss later in this chapter, the ganglia innervating reproductive organs are quite different.

Divisions of the Autonomic Nervous System: Functional Differences

The sympathetic and parasympathetic nervous systems differ not only in their anatomy but also in their physiology and behavioral context of activation. These are summarized for the male reproductive organs later in this chapter. Specific brain circuits and mechanisms determine the type and duration of sympathetic and parasympathetic activity to ensure that relevant types of nerves are activated or inhibited appropriately. Many areas of the brain are involved in sexual and reproductive function, especially the hypothalamus and limbic system; specific regions of relevance include the paraventricular nucleus and medial preoptic area of the hypothalamus, ventral tegmentum, medial amygdala, and periaqueductal gray (Clement and Giuliano, 2016; Jänig, 2008).

Sympathetic and parasympathetic nerves generally have different, and often opposing, effects on shared or related organ targets (Jänig, 2008). This is most often caused by differential tissue-selective targeting of effectors in the organ. For example, in the vas deferens, sympathetic nerves innervate the smooth muscle, whereas parasympathetic nerves innervate the epithelium (Fig. 2A). When considered across the spectrum of actions across the body, the sympathetic nervous system is often described as enabling a 'fight-or-flight' response, with a range of activities that can be synchronized to optimize the response to a physical challenge (e.g., increasing heart rate and diverting blood flow from the gut to the limb muscles). Conversely, the function of the parasympathetic nervous system function is often generalized as 'rest-and-digest', because it has effects such as decreasing heart rate and redirecting blood from the limb muscles to the gut. These two terms are very relevant to some situations, but do not capture the full scope of autonomic nerve functions that are essential for numerous readjustments of tissue and organ function throughout every hour and day of our lives. More relevant to this chapter, these two terms cannot be readily applied to functions of the urogenital system, where the autonomic nervous system is instead critical for mediating reproductive behaviors, voiding and continence.

Sympathetic and parasympathetic ganglion neurons generally use different neurotransmitters to communicate at synapses with their target tissues (neuroeffector junctions) (Fig. 1). Neurotransmitters have transient actions close to their site of release from the axon, as they are released in small amounts and either metabolized or resorbed by nearby tissues. The primary neurotransmitter released by parasympathetic axons in the organs is acetylcholine (ACh), so events activated by this transmitter are referred to as

Fig. 2 Sympathetic and parasympathetic axons in the vas deferens and their cell bodies in pelvic ganglia. Panel **A** shows part of a transverse section through the rat vas deferens, using fluorescence immunohistochemistry to reveal the location of cholinergic parasympathetic axons (green) in the lamina propria, labeled with an antibody to vesicular acetylcholine transporter, and noradrenergic sympathetic axons (magenta) in the muscle, labeled with an antibody to tyrosine hydroxylase. The inset is a higher magnification view of axons in the muscle to illustrate the swellings (varicosities) that aggregate and release neurotransmitter. Here the noradrenergic axons were labeled with an antibody to a co-expressed peptide (neuropeptide Y) instead of tyrosine hydroxylase. Panel **B** shows part of a pelvic ganglion from a male mouse, using fluorescence immunohistochemistry to show the intermingling of cholinergic (green) and noradrenergic (magenta) neurons, using an antibody to nitric oxide synthase (that synthesizes nitric oxide, a co-transmitter with acetylcholine) and tyrosine hydroxylase. Calibration bar represents 50 μm (A), 15 μm (inset) and 30 μm (B).

cholinergic. ACh acts by binding to one or more subtypes of muscarinic cholinergic receptors expressed in tissues innervated by parasympathetic axons. It is common, however, for additional transmitters (co-transmitters) to be released at the same time from the same axons. These include nitric oxide (NO), adenosine triphosphate (ATP) and various neuropeptides (e.g., vasoactive intestinal peptide). In some tissues, the actions of co-transmitters can dominate over the actions of ACh. The primary sympathetic transmitter released in most tissues is norepinephrine (synonym: noradrenaline). Norepinephrine acts by binding to one or more subtypes of adrenoceptors; this is referred to as noradrenergic transmission. As discussed for the parasympathetic nerves, additional transmitters (such as ATP and neuropeptide Y) can also be released from many sympathetic axons. Some classes of sympathetic ganglion neurons—such as sympathetic nerves that activate secretion from sweat glands—release ACh but are not defined as parasympathetic as they receive input from thoracolumbar (i.e., sympathetic) preganglionic neurons.

There are several other ways in which neurotransmitter receptors can be activated in the organs. The first is relevant to the adrenoceptors. When the adrenal medulla is activated, high levels of norepinephrine and epinephrine (synonym: adrenaline) are released into the bloodstream. Therefore, any tissues that express adrenoceptors will be potentially affected. The second relates to cholinergic receptors (synonym: cholinceptors) and adrenoceptors expressed by autonomic neurons that function as autoreceptors on autonomic axons within the organs. Effects on these receptors by transmitters or circulating ligands have a range of complex positive- and negative-feedback effects on transmitter release. Therefore, to develop pharmaceutical therapies targeted to specific tissues or organs, a detailed understanding of these complex signaling scenarios is essential. These are confounded by species differences. Although many of the broad principles of autonomic regulation are shared between laboratory animals and people, there is diversity in the range of substances released by autonomic nerves (e.g., the types of neuropeptides), the dominant receptor subtypes expressed by the organs and their signaling mechanisms.

Autonomic Regulation of Male Reproductive Organs

The Pelvic Ganglia (Inferior Hypogastric Plexus)

The pelvic ganglia (synonym: inferior hypogastric plexus) contain all the parasympathetic and most of the sympathetic neurons that regulate the urogenital organs (Keast, 1999b; Keast, 2006). A small proportion of sympathetic innervation originates from other sympathetic ganglia, i.e., the lumbosacral sympathetic chain ganglia and the inferior mesenteric ganglion. An example is the sympathetic innervation of the corpus cavernosum that originates from the sympathetic chain. The pelvic ganglia also contain sympathetic and parasympathetic neurons that innervate the large intestine, supplementing the enteric nervous system.

The pelvic ganglia are very unusual autonomic ganglia because they contain both sympathetic and parasympathetic neurons (Figs. 2B and 3). In humans, these ganglia are aggregated into a complex network of microganglia called the inferior hypogastric plexus (Baader and Herrmann, 2003). Although they are intermingled within these ganglia, the sympathetic and parasympathetic ganglion neurons receive their commands from preganglionic neurons with different locations (sympathetic from the thoracolumbar level and parasympathetic from sacral level). The two main structures that carry these commands from the relevant spinal levels are the hypogastric nerves (sympathetic) and the pelvic nerves (parasympathetic; synonym, pelvic splanchnic nerves). These two

Fig. 3 Sympathetic and parasympathetic components of pelvic ganglia. Diagram shows the two types of spinal input to the pelvic ganglia, from sympathetic and parasympathetic preganglionic neurons that lie in the intermediolateral nucleus in two distinct spinal levels. The lumbar segments that form the lumbar enlargement separate these two sources of preganglionic neurons. The particular spinal levels have not been specified here as there are species differences in the number of lumbar and sacral spinal segments and, within these regions, which particular segments contribute to sympathetic and parasympathetic outflow. Sympathetic and parasympathetic postganglionic axons travel together in nerves that connect to the relevant organs. *IML*, intermediolateral nucleus.

nerves converge upon the pelvic ganglia, where their individual axons then make a synaptic connection with the appropriate ganglion neuron (or group of neurons). A minority of sympathetic ganglion cells in the pelvic ganglia use ACh as their primary transmitter, rather than norepinephrine (note: these neurons are defined as sympathetic because they are controlled by the thoracolumbar preganglionic neurons rather than sacral preganglionic neurons).

The unusual intermingling of sympathetic and parasympathetic neurons provides a challenge to understanding their development, connectivity, function and impact of disease or injury. In many species, including humans, this is made even more difficult because their pelvic autonomic neurons are not in discrete, large ganglia but embedded within a dispersed plexus that extends between and even within the outer layers of the pelvic organs. The breadth and complexity of this structure poses a considerable challenge to surgical procedures in these organs (Baader and Herrmann, 2003). Experimental studies on pelvic ganglia have instead focused on rats and mice, where the equivalent neurons are aggregated into a large, single ganglion on each side of the animal (Keast, 1999b). This simplicity enables precise experimental interventions and quantitative studies to be performed. Pelvic ganglia contain many more neurons in males than females, correlating with the higher density of autonomic axons in the reproductive organs in males. It is not known when this sexual dimorphism develops or how it is initiated.

Autonomic Reflexes and Male Sexual Function

The major role of sympathetic nerves in the male reproductive organs is to contract smooth muscle, whereas parasympathetic nerves enhance secretions and dilate the specialized vascular bed of the corpus cavernosum to cause penile erection. Therefore, to enable the full sequence of events—erection, emission and ejaculation—it is essential to coordinate activation of sympathetic and parasympathetic pathways (Andersson, 2011; Clement and Giuliano, 2015; Clement and Giuliano, 2016; Young et al., 2009). Moreover, ejaculation is not mediated purely by the autonomic nervous system. Complete expulsion requires carefully timed activation of striated perineal muscles that are innervated by sacral spinal motor neurons, not autonomic ganglia. Therefore, involuntary and voluntary components of the nervous system collaborate to complete this entire behavior. An additional autonomic function in each of the reproductive organs is control of tissue perfusion by regulation of vascular tone, specifically via activation of sympathetic vasoconstrictor axons.

Specific brain and/or spinal neural circuits contribute to each component of sexual function. In the case of erectile function, optimal strength and duration of erection occur if two components are activated. Direct, mechanical stimulation of the penis or

genital area activates sensory pathways that initiate activity in the sacral spinal preganglionic pathways to cause erection. This 'reflexogenic erection' is usually accompanied by 'psychogenic erection' that involves the brain, driven by awareness of erotic context, visual, auditory and olfactory stimuli. Psychogenic erection also involves more rostral levels of the spinal cord (lower thoracic and upper lumbar).

Emission, namely the release and propulsion of seminal fluid through the ejaculatory ducts to the urethra, involves spinal rather than brain circuits, especially the sympathetic pathways. Activation of these pathways causes contraction of smooth muscle of the ducts, prostate gland and seminal vesicles. The role of the parasympathetic nervous system here is unclear. The production of seminal fluid is most likely regulated by parasympathetic axons innervating various glandular epithelia, but it has yet to be determined how the activity of these nerves changes during sexual behavior. Expulsion involves a mixture of sympathetic spinal pathways to control smooth muscle of the ejaculatory ducts, bladder neck and proximal urethra. Both brain and spinal mechanisms integrate this with sensory stimuli from the genitals to coordinate the smooth muscle activity with rhythmic contractions of pelvic striated muscles. The spinal neurons involved in this coordination lie in the 'spinal ejaculation generator', a cluster of neurons in the mid-lumbar spinal cord. These neurons have a strong connection to the thalamus, a major sensory input center of the brain.

In addition to this integrated sequence of events in the reproductive system, there is further coordination with the neural circuits of the lower urinary tract. By contracting the smooth muscle of the bladder neck and pelvic (proximal) urethra, retrograde flow of seminal fluid is prevented during emission and ejaculation. The logistics of this coordination have not been defined, but likely involve a mixture of spinal and brain mechanisms. Central nervous system mechanisms also inhibit voiding reflexes of the lower urinary and digestive tracts during sexual activity.

Neural Communication with Tissues in Male Reproductive Organs

Across the tissues and organs of the male reproductive organs, there is diversity in the distribution and density of sympathetic and parasympathetic axons, and in the associated neurotransmitter receptor combinations that act as neuroeffectors. Nevertheless, these axons all share a common structure. Each autonomic axon branches near its point of termination, enabling simultaneous control of many cells at once by release of transmitter at multiple sites (Brock and Cunnane, 1993). Each of these terminal branches has numerous small swellings (varicosities) (Fig. 2A). Varicosities are functionally equivalent to synaptic boutons found on axons of the central nervous system. They serve as neuroeffector junctions where neurotransmitters are stored until being released, when an electrical signal (action potential) has reached the final length of axon. Each autonomic axon may have hundreds of varicosities, therefore transmitter can be released from many sites at one time.

Although the sites of transmitter release can be deduced from the location of varicosities, there is no easily visible structural specialization of the synapse on the cell that is innervated by an autonomic axon. This contrasts with the classical neuromuscular junction in skeletal muscle that has a single large transmitter release site adjacent to a highly folded region of membrane near the centre of the muscle cell. Also, sympathetic and parasympathetic axons look identical. Therefore, the precise sites and properties of autonomic communication in an organ can only be identified by electrophysiological, pharmacological or microscopic anatomy experiments.

The best characterized actions of autonomic nerves will be summarized here. Many other possible roles continue to be proposed and explored. This list has not included sympathetic vasoconstrictor axons that are present in each organ.

Testicular tissue does not have significant autonomic innervation beyond its vasculature. In the smooth muscle wall of the epididymis there is a pro-contractile sympathetic nerve supply. These axons increase in density towards the vas deferens. Parasympathetic axons are sparse or absent in these tissues. Of all regions in the male reproductive system, the testis and epididymis are the least dependent on autonomic nerves for their primary function.

The vas deferens has a thick muscular wall and high density of sympathetic noradrenergic axons that cause a strong contraction after electrical or pharmacological activation. Parasympathetic cholinergic axons are sparsely distributed in the muscle but form a dense network in the lamina and near the epithelium. The function of these parasympathetic axons is not known, but elsewhere in the body, parasympathetic activity stimulates epithelial secretion. These two contrasting patterns of innervation are shown in Fig. 2A. The seminal vesicles and bulbourethral glands show a comparable pattern, i.e., sympathetic noradrenergic pro-contractile innervation of smooth muscle and blood vessels, with a sparser parasympathetic cholinergic pro-secretory innervation of the epithelium.

In the prostate gland, sympathetic noradrenergic axons dominate and form a dense network within the smooth muscle trabeculae and stroma, as well as regulating vascular tone. Parasympathetic cholinergic axons primarily innervate the epithelial cells but their physiological role is less well understood. Studying prostate innervation is complicated by differences in structure and function across prostatic regions, and corresponding differences in axon density between these regions.

Penile erection and detumescence are complex physiological processes that require coordinated changes in blood flow across several vascular beds (Andersson, 2011). Erectile tissues of the corpora cavernosa and corpus spongiosum of the penis comprise networks of thin-walled vessels, filling of which causes erection. In total, this process involves increasing the blood flow to the penis, relaxing the smooth muscle of these thin-walled vessels and blocking the outflow of blood from the penis to sustain an increased intracavernosal pressure.

The primary driver for the active relaxation of intracavernous vessels is the parasympathetic nervous system, although there may also be some sympathetic component. Signals from sacral preganglionic neurons activate parasympathetic pelvic ganglion neurons that innervate the erectile tissue, releasing transmitters ACh and nitric oxide. Nitric oxide directly relaxes cavernosal smooth muscle

by activating the enzyme, guanylate cyclase, to synthesize cyclic GMP (cyclic guanosine monophosphate) from GTP (guanosine-5'-triphosphate). This cyclic nucleotide second messenger causes cavernosal smooth muscle relaxation. In contrast, ACh causes cavernosal muscle relaxation indirectly, by activating muscarinic ACh receptors on the endothelium (vessel lining) that in turn release nitric oxide; this causes further dilation of the cavernosal spaces. Many commonly used drugs that enhance erection have their primary action by increasing cyclic GMP levels within the cavernosum. Detumescence is triggered by activity of sympathetic nerves that release noradrenaline to contract the smooth muscle of cavernosal vessels and enhance the exit of blood from the penile vasculature. In the flaccid state, these sympathetic nerves provide a tonic contraction of the cavernosal smooth muscle. Striated muscles involved in ejaculation are controlled by the somatic nervous system but also contain some autonomic nerves, the physiological role of which during sexual behaviors has not been examined in depth.

Until this point, the focus of this chapter has been how nerves communicate with organs. There are also powerful ways that the organs communicate with nerves. For example, many tissues synthesize trophic factor proteins that during development are critical for establishing the appropriate axon connections and, by triggering signals back to the neuronal cell body in the autonomic ganglion, allowing the neuron to survive (Glebova and Ginty, 2005). Even in adulthood, any reduction in access to trophic factor has an impact on neuronal health. Therefore, if axon connections to an organ are damaged, these trophic signals can no longer reach the neuronal cell bodies in the ganglia. This is very relevant to developing strategies for restoring function.

Sensory Innervation of Male Reproductive Organs

Sensory nerves have a much lower density in the male reproductive organs than in the lower digestive or urinary tracts. The contrast is even greater for the genital skin—as the glans penis has one of the highest densities of sensory axons found anywhere in the body. Within the male reproductive organs, the sensory axons are greatly outnumbered by autonomic axons.

Sensory nerves supplying the reproductive organs originate from neuronal cell bodies in lumbar and sacral dorsal root ganglia. These particular sensory nerves have not undergone extensive study, but from studies of sensory nerves in the urinary and digestive system, it is predicted they would have the capacity to detect mechanical (e.g., distension) and chemical changes (e.g., inflammatory mediators or pH changes with tissue damage).

It is not known if sensory axons have a role in coordinating the components of normal sexual reflexes, but it is possible that they activate local reflex loops, functioning to detect the passage of seminal fluid (distension or flow detectors) or its contents (chemoreceptors). They also likely have roles in inflammatory conditions and several types of pelvic pain (Schwartz et al., 2015).

Sensory axons connecting with the reproductive organs project in the same nerve bundles as autonomic axons—the hypogastric and pelvic nerves, and the nerves that connect pelvic ganglia with the organs. Therefore, they are similarly vulnerable to injury or disease. In addition, several studies have proposed that some sensory neurons have branched axons that innervate both the bladder and the prostate. This raises the possibility that disease or damage in the bladder could impact on prostate function, or vice versa.

Effects of Gonadal Hormones on Autonomic Neural Circuits

The field of reproductive neuroendocrinology is strongly focused on regions of the brain, especially the hypothalamus and pituitary. However, many peripheral neurons that regulate autonomic function of the reproductive organs express proteins relevant to steroid signaling, such as androgen receptors (ARs), estrogen receptors (ERs) and aromatase (Purves-Tyson et al., 2007). These are expressed in subpopulations of neurons in the pelvic ganglia, lumbosacral dorsal root ganglia and spinal cord (Keast, 2006). Because of the many possible sites of action for circulating or exogenously administered steroids, it can be challenging to define exactly how a steroid affects each aspect of sexual function. Another layer of complexity is that steroids can stimulate synthesis of neurotrophic factors by the organs. Therefore, an effect of steroid exposure or deprivation on a peripheral neuron could be occurring directly on that neuron or indirectly via modulation of organ-derived trophic factors.

The impact of steroid exposure on pelvic ganglion neurons has been examined experimentally for only a limited number of functions. In rodent pelvic ganglion neurons that express ARs and ERs, there is a critical period for androgen exposure in the perinatal period, when various adult features of these circuits are established, and further changes at puberty (Brock et al., 2007; Keast, 1999a; Keast, 2006). Post-pubertal reduction in androgen exposure — whether by gonadectomy or pharmacological/genetic intervention — has a noticeable impact on neural features as diverse as cell body size, axon branching, neuropeptide and transmitter expression, capacity for regrowth after injury, and electrophysiological properties. Typically, these are reversible by subsequent exposure to androgens, or in some cases, estrogens.

The Relevance of Autonomic Nerves to Clinical Conditions in the Male Reproductive Organs

Many clinical conditions are caused by changes in the structure or activity of autonomic nerves, leading to organ dysregulation. The conventional therapeutic approach for autonomic systems has been to develop drugs that selectively activate or block particular classes of axons or transmitter signaling processes. There is now increasing interest in bioengineering approaches to modulate peripheral autonomic activity, by using implantable devices to electrically stimulate or block activity in specific types of axons (Famm et al., 2013).

A contributor to disorders of male reproductive organs is the reduction of activity of autonomic nerves, which may be caused by diverse neurodegenerative conditions such as diabetes and various small-fiber neuropathies (Dineen and Freeman, 2015). The

underlying pathophysiology is best characterized in the context of erectile dysfunction, but can also affect other urogenital organs leading to ejaculatory problems, lower urinary tract symptoms, and other clinical conditions. It is popular to focus therapies on enhancing the capacity of existing nerves, e.g., Viagra (sildenafil) for enhancing nitric oxide signaling in erectile tissue of the penis, but there is also interest in developing ways to protect autonomic nerves from degeneration or to enhance tissue perfusion by neural regulation of the microvasculature. The impact of hormonal environment on sexual function and clinical dysfunction also includes a component due to the effects of hormones on relevant autonomic nerves (Podlasek et al., 2016).

Autonomic regulation and sensory innervation of the reproductive organs is physically at risk during pelvic surgery (e.g., prostatectomy), commonly performed to remove malignant tissue. The complex anatomy of the inferior hypogastric plexus and its connections makes it extremely difficult to perform such surgery without injuring these nerves (Baader and Herrmann, 2003). Erectile dysfunction and impaired bladder control are the most common negative outcomes. Surgical procedures and methods continue to be improved to visualize this plexus in situ, but in some cases the location and extent of tissue removal required make it impossible to avoid some neural damage. Improved understanding of endogenous trophic factors that originally enabled these nerve-organ connections to be established during development has provided some strategies for enhancing their recovery after damage or degenerative triggers.

Clinical conditions that potentially benefit from reduction of autonomic or sensory activity in the reproductive organs have largely focused on the prostate gland and lower urinary tract but may have complex interactions with sexual dysfunction (Mazur et al., 2012). Lower urinary tract symptoms, comprising a spectrum of voiding disorders often age-related and coupled with benign prostatic hyperplasia, can be attenuated by blocking sympathetic activation of prostatic (and potentially urethral) smooth muscle. While this approach still has limitations of efficacy and specificity, additional ways of regulating smooth muscle tone in the prostate are still being explored. The actions of inflammatory mediators on these autonomic nerves and their neighboring sensory nerves are strongly implicated in neuronal overactivity and increased sensitivity of these urogenital sensory nerves to normal physiological stimuli. This is relevant not only to lower urinary tract symptoms but also pelvic pain driven by prostatitis.

There is growing interest in the concept that autonomic nerve effects on organ structure could be manipulated to reduce the growth of cancer. This is being explored in several types of cancer, including the prostate (Saloman et al., 2016). The original rationale for this approach was the observation that removing the nerve supply to a healthy prostate gland, or pharmacologically blocking the activity of these nerves, impacts on the structure of prostate glandular or stromal tissue. The nature of the effect depends on the type of nerve manipulation and the duration of intervention. It is logical to now investigate the impact of selectively blocking or stimulating the activity of various types of autonomic nerves in a situation of unregulated tissue growth.

Introduction

The circadian (circa = about, dia = day) clock controls 24-h rhythms of physiological processes, including sleep/wake behavior, hormone levels, and body temperature. In the presence of rhythmic external stimuli, the circadian clock functions to synchronize the physiology and behavior of the organism with that of the environment. An essential attribute of circadian rhythms is not only that they synchronize, or entrain, to timing cues, but they also persist in the absence of these timing cues in constant conditions, such as constant darkness or constant light. Animals will continue to exhibit a rhythmic “period” around 24 h in these constant conditions.

For most organisms, light is the primary time cue for the circadian clock. In mammals, the master clock is located in the suprachiasmatic nucleus (SCN), a nucleus in the ventral hypothalamus of the brain, just dorsal to the optic chiasm. As light enters the eye and activates specialized retinal ganglion cells, this light information is sent to the optic chiasm via neuronal projections known as the retinohypothalamic tract. Then, the light information is conducted to the SCN and is interpreted by the animal’s internal circadian clock via complex molecular mechanisms (see Fig. 1).

The circadian clock responds to external timing cues, primarily light, because of the molecular components that exist in positive and negative molecular feedback loops, which oscillate in a 24-h rhythm. The proteins, translated from core clock genes, are essential for generating and regulating other circadian rhythms both within and outside of the SCN. The positive element of the feedback loop begins with the proteins CLOCK and BMAL1, which form the CLOCK:BMAL1 pair (i.e. heterodimer). Once the CLOCK:BMAL1 complex is formed, it associates with *E*-box promoter regions, located upstream of the gene, and promotes transcription of the clock genes *Period* (*Per*) and *Cryptochrome* (*Cry*). The negative feedback loop is achieved by the heterodimerization of PER and CRY proteins. Specifically, *Per* and *Cry* are translated in the cytosol, where their protein counterparts form a PER:CRY heterodimer. Then, the PER:CRY pair translocates back into the nucleus, where it inhibits the binding of CLOCK:BMAL1 to promoter regions, ultimately decreasing transcription of *Per* and *Cry*. This process takes approximately 24 h to complete one cycle, resulting in the rhythmic expression of the circadian genes and proteins. CLOCK:BMAL1 also binds to the *E*-box elements of other genes to regulate their transcription, generally known as clock controlled genes, which can influence downstream effects of the circadian timekeeping system, as well as fine-tune the expression of core clock genes. Furthermore, while the core clock gene loop located in the SCN is known as the master clock, this same molecular loop has been shown to occur in tissues throughout the body. (See Fig. 2.)

Circadian rhythms are an important research area for understanding reproductive physiology of both males and females, with circadian variations in sex steroid hormones, critical enzymes involved in steroidogenesis, mating behavior and receptivity, and other important factors involved in regulation of the reproductive system. Importantly, the core circadian molecular clock can be measured in almost all peripheral systems. However, the exact role that the circadian timekeeping system plays in regulating male reproduction remains poorly understood. This chapter will specifically examine the evidence for the presence of clock systems in different male reproductive tissues and functions, with emphasis on mice and rat studies. Specifically, we will focus on rhythms found in the testes, where spermatogenesis occurs, the epididymis, where sperm maturation occurs, and accessory glands and ducts, which aid in male reproductive function and sperm health. Additionally, we will discuss evidence for the male reproductive system acting on the circadian timekeeping system to fine tune behavior.

Rhythms of Circadian Clock Genes and Proteins in Testis

A handful of studies have identified rhythmic clock gene expression in the rodent testis. One early mouse study investigating mRNA expression found that the clock genes *mPer1* and *mPer2* exhibited daily rhythmic expression, peaking around 6 (*mPer1*) and 9 (*mPer2*) hours after lights on (Zylka et al., 1998). This rhythmic expression of clock genes in the testes was confirmed in a second

Fig. 1 Simplified schematic of the circadian timekeeping system. Light enters through the eye and stimulates the retina. Then, timing information from the light stimulus is communicated through the retinohypothalamic tract (RHT) to the hypothalamus. Within the hypothalamus, a specific subset of neurons located in the suprachiasmatic nucleus (SCN) are stimulated. Using either endocrine outputs or neuronal projections, the SCN communicates the light information to the rest of the brain and body to initiate multiple output rhythms. Specifically, this light information relayed by the SCN can regulate locomotor and reproductive behaviors, sex steroidogenesis, and gene and protein expression within the male reproductive system.

Fig. 2 Core circadian clock feedback loops. In the nucleus, the CLOCK:BMAL1 protein pair binds to E-box elements located upstream of the *Period* (*Per*) and *Cryptochrome* (*Cry*) genes. This binding initiates the transcription of the clock genes *Per1* and *Cry1*, where they then are translated into their respective proteins, PER and CRY. PER and CRY bind in the cytosol to form the PER:CRY pair, and then translocate back into the nucleus. In the nucleus, PER:CRY can bind to and inhibit the action of CLOCK:BMAL1, therefore inhibiting their own expression. The expression of BMAL1 can be further finetuned by additional clock genes and proteins. Specifically, CLOCK:BMAL1 binds to the E-box elements upstream of the genes for *Rev-erbα* and *Rora*, initiating transcription of these two genes. Then, the RORA and REV-ERBα proteins are translated in the cytosol, where they can re-enter the nucleus and affect *Bmal1* gene transcription. Specifically, RORA and REV-ERBα bind to ROR elements (RORE) located upstream of the *Bmal1* gene where they initiate or inhibit transcription of the *Bmal1* gene, respectively. Overall, this precise timing of gene transcription and protein translation results in the daily rhythmic expression of the core molecular clock. Furthermore, CLOCK:BMAL1 can bind to additional E-box elements upstream of other circadian target genes known as clock-controlled genes (CCGs), thereby initiating transcription of genes outside of the core circadian clock loop. Importantly, this core circadian molecular loop is found within almost every tissue of the body and is thought to be important for regulating precisely timed events within those tissues.

study in mice (Bebas et al., 2009). In this study, rhythmic expression of the clock genes *mPer1*, *mPer2*, and *Bmal1* was found, with levels peaking in the middle-to-late night. Interestingly, this study did not observe rhythmic expression of mPER1 and BMAL1 protein expression. While both of these studies showed rhythmic expression of core circadian clock genes, the peak in expression of *mPer2* was opposite in timing (phase) between the two studies. Additionally, these studies documented clock gene rhythmicity in the male reproductive tract; however, they did not examine the functional role of rhythmic clock gene expression in the testis, which remains to be investigated.

Interestingly, additional studies examining the presence of rhythmic circadian clock gene expression have produced conflicting results. In one study, expression of the clock genes *mCry1*, *mCry2*, and *mPer1* was observed in the mouse testis; however, this expression was not rhythmic for any of these genes (Miyamoto and Sancar, 1999). An additional study investigated rhythmicity of *mPer1* in several endocrine tissues, including the mouse testis, using in situ hybridization, a technique that allows for the visualization of labeled nucleic acids in a section of tissue (Bittman et al., 2003). In this study, they did not observe rhythmic expression of the clock gene *mPer1*. However, they did observe daily rhythmic expression of mPER1 protein in specific sections of the seminiferous tubules, the portion the testes where spermatozoa are found. This finding indicates differential expression based on location. In another study, the expression of *mPer1* and *Clock* genes and proteins was observed in mouse testes; however, the expression was also not rhythmic (Morse et al., 2003). Moreover, this study found that *mPer1* and *Clock* were expressed in different portions of the seminiferous tubules. Overall, these studies observed that the traditional clock genes and proteins are expressed in the testes, albeit not rhythmically, potentially indicating a potential non-circadian function of these genes.

The conflicting results of whether or not there are circadian rhythms in gene and protein expression in the testes have yet to be resolved. However, it is important to note that most of these studies examined expression using whole testes. The testis is a very

diverse organ, with many cell types present, including seminiferous tubules, developing spermatozoa, interstitial cells, and Sertoli cells. It is possible that clock gene and/or protein expression is rhythmic in one or all of these different cell types. Alternatively, it is possible that circadian expression of these clock genes and proteins only occurs in some of these cell types, or at specific developmental time points. Indeed, one study using mice observed that *mPer1* was expressed in specific stages of spermatogenesis, specifically in the spermatids and not in the spermatogonia and spermatocytes (Morse et al., 2003). This study, among others, reiterates the importance of investigating rhythms of gene and protein expression at specific developmental time points may be a critical next step to understanding the circadian clock system in the testis.

Rhythms of Circadian Clock Genes and Proteins in the Epididymis, Accessory Glands, and Vas Deferens of the Male Reproductive Tract

Until recently, it has been unclear if there was a role for circadian genes in other tissues of the male reproductive tract beyond the testes, including the epididymis, accessory glands (i.e. seminal vesicles and prostate gland), and vas deferens. These tissues are essential for the further maturation and health of spermatozoa, production of semen, and the release of sperm during ejaculation, respectively. In addition to investigating the rhythmic expression of genes in the testes, one study also measured gene and protein expression of *mPer1*, *mPer2*, and *Bmal1* in the epididymis, vas deferens, seminal vesicles, and prostate gland (Bebas et al., 2009).

Interestingly, rhythmic gene and protein expression varied in the epididymis for all genes, depending on where the expression was measured. In the caput (head) of the epididymis, *mPer1* gene expression was rhythmic, peaking at 8 h after lights off, while mPER1 protein expression peaked 2 h after lights on. While *Bmal1* gene expression was not rhythmic in the caput epididymis, BMAL1 protein expression did have a daily expression pattern, with a peak 2 h after lights off. In the corpus (body) of the epididymis, they observed rhythmic expression of both *mPer1* and *mPer2* clock genes and mPER1 clock protein, all peaking 2 h after lights off. They also observed rhythmic *Bmal1* gene expression in the corpus, with an opposite timing (phase) to that of *mPer1*/*mPer2*, peaking in the late night. BMAL1 protein expression was rhythmic in the corpus, with a peak in expression at 2 h after lights on. In the cauda (tail) of the epididymis, *Bmal1* and *mPer1* were rhythmic and in phase with each other, peaking 8 h after lights off, while *mPer2* peaked 2 h after lights off. Overall, these data indicate that there are rhythms in the expression of clock genes and clock proteins throughout the epididymis, a tissue where further maturation of spermatozoa occurs. Furthermore, within each location within the epididymis, they observed that peak BMAL1 protein expression followed peak mPER1 expression, consistent with what is expected if BMAL1 is acting as the positive regulator in the circadian feedback loop.

Like the epididymis, this study also found rhythmicity in clock gene and protein expression throughout the accessory glands and vas deferens, with tissue-specific expression of genes. In the vas deferens, they found *mPer1* and *mPer2* gene expression peaked at 4 h before lights off and *Bmal1* gene expression peaked 2 h after lights on, with respective protein levels peaking at the same time. In the prostate, *mPer1* and *mPer2* both peaked 8 h after lights on, while *Bmal1* peaked 8 h after lights off, with mPER1 protein peaking at 8 h after lights on and BMAL1 protein peaking around 2 h after lights off. Overall, they found no significant rhythms in the seminal vesicles, however, both *mPer1* and *mPer2* genes and mPER1 and BMAL1 proteins were highly expressed. Together, these data show rhythmic expression of core circadian clock genes in a tissue-specific manner. It is plausible that the rhythmic expression of the core circadian genes and proteins is involved in regulating timed events in the male reproductive tract, including sperm maturation and hormone production. However, the functional role of these genes in the male reproductive tract remains to be examined (Table 1).

Traditional Clock Genes Have Non-Circadian Functions for Spermatogenesis

The continuous production of sperm throughout the reproductive lifetime of the male is essential for fertility. Spermatozoa develop with specific spatiotemporal patterning along the length of the seminiferous tubule. Briefly, the most undifferentiated cells, the spermatogonia, are located basally, while the more mature spermatids are located toward the lumen of the testis. While circadian rhythmicity in developing spermatozoa has been studied, more precise tools are needed to further evaluate individual components and specific locations that exhibit rhythmicity. In one study, location-specific expression of *Per1* was visualized with in situ hybridization (Morse et al., 2003). Using this technique on stage-specific samples of dissected tubules showed that *mPer1* expression was highest in the middle of the seminiferous tubules, where elongated spermatids and spermatozoa reside. To determine if *mPer1* expression is driven by the traditional CLOCK/BMAL1 dimer mechanism, the authors used in situ hybridization to measure *Clock* expression. They found that *Clock* was expressed at different locations along the tubule compared to expression of *mPer1*. Specifically, *Clock* was expressed in the periphery of the tubule, where spermatogonia and primary spermatocytes are located. In *Clock* mutant mice (without a functioning *Clock* gene), *Per1* expression persisted, indicating that *Per1* is expressed independently of *Clock* expression. Overall, it appears that *Per1* is differentially expressed relative to sperm development stages and suggesting it may not be related to circadian functions.

Interestingly, another group released similar results around the same time as Morse et al., except observing protein expression of CLOCK and mPER1 using immunohistochemistry, as opposed to mRNA expression (Alvarez et al., 2003). Immunohistochemistry allows for visualization of proteins in specific sections of tissues using labeled antibodies. Using this technique, they observed noncyclic expression of mPER1 at different stages of spermatogenesis depending on the age of the animal. In early postnatal testes (postnatal day 7), they observed that expression of mPER1 was restricted to spermatogonia in early stages (Type A spermatogonia)

Table 1 Summary of the rhythmic expression of clock genes and proteins observed in the male reproductive tract of mice

<i>Tissue</i>	<i>Gene or protein</i>	<i>Rhythms present?</i>	<i>Description of rhythms observed</i>	<i>References</i>
Testis	<i>Per1</i>	Yes	Peak 6 h after lights on Peak in late night	Zylka et al. (1998) Bebas et al. (2009)
		No rhythmic expression		Bittman et al. (2003) and Morse et al. (2003)
	<i>Per2</i>	Yes	Peak 9 h after lights on Peak in late night	Zylka et al. (1998) Bebas et al. (2009)
	<i>Bmal1</i>	Yes	Peak 8 h after lights off	
	<i>Cry1</i>	No rhythmic expression		Miyamoto and Sancar (1999)
	<i>Cry2</i>			
	<i>Clock</i> PER1 BMAL1			Morse et al. (2003) Bebas et al. (2009) and Bittman et al. (2003)
Epididymis	<i>Per1</i>	Yes	Caput (head): Peak at 8 h after lights off; Corpus (body): Peak in late morning; Cauda (tail): Peak at 8 h after lights off	Bebas et al. (2009)
	<i>Per2</i>		Corpus (body): Peak in the late morning/early night; Cauda (tail): Peak 2 h after lights off	
	<i>Bmal1</i>		Caput (head): No rhythmic expression; Corpus (body): Peak in the late night, in opposite phase of <i>mPer1</i> and <i>mPer2</i> in the corpus; Cauda (tail): in phase with <i>mPer1</i> , peak 8 h after lights off	
	PER1		Caput (head): Peak 2 h after lights on; Corpus (body): Peak 2 h after lights off	
	BMAL1		Caput (head): Peak 2 h after lights off; Corpus (body): Peak 2 h after lights on	
Vas deferens	<i>Per1</i>	Yes	Peak 4 h before lights off	
	<i>Per2</i>			
	<i>Bmal1</i>		Peak 2 h after lights on	
	PER1		Peak 4 h before lights off	
	PER2 BMAL1		Peak 2 h after lights on	
Prostate	<i>Per1</i>	Yes	Peak 8 h after lights on	
	<i>Per2</i>			
	<i>Bmal1</i>			
	PER1 BMAL1		Peak 2 h after lights off	
Seminal vesicles	<i>Per1</i>	No rhythmic expression		
	<i>Per2</i>			
	PER1			
	BMAL1			

and then this expression transitions and mPER1 is found in spermatocytes at postnatal day 14. In adult samples, mPER1 expression was only observed in spermatogonia in later stages of development (Type B spermatogonia) and condensing spermatids in adult seminiferous tubule. To evaluate if CLOCK is involved in regulating mPER1 expression in the seminiferous tubules of adults, CLOCK expression was localized and compared with mPER1 expression. Interestingly, CLOCK was expressed in the acrosome (the cap of the sperm head) of round spermatids and did not colocalize with mPER1, and was also found in different sections of the seminiferous tubules. These data indicate a differential function of these clock proteins compared with the SCN and other peripheral tissues that exhibit the canonical core circadian clock loops. While the function for the developmental stage-specific expression of mPer1 mRNA and protein remains unknown, recent studies suggest non-circadian functions for Clock expression in sperm. Indeed, using molecular techniques to reduce or knock down CLOCK expression in the adult mouse testis results in reduced fertility, potentially by indirectly reducing acrosin activity in sperm (Cheng et al., 2016).

Rhythms in Steroidogenesis

The production and secretion of gonadal hormones are tightly regulated by the hypothalamic-pituitary-gonadal axis. Small-bodied neurons in the hypothalamus release gonadotropin releasing hormone (GnRH), which acts upon receptors in the anterior pituitary

to stimulate the synthesis and release of the gonadotropins luteinizing hormone (LH) and follicle stimulating hormone (FSH) into circulation. These gonadotropins act differentially within the testis to stimulate synthesis and release of sex steroid hormones, including testosterone. The primary action of LH is to stimulate production of the androgen hormones, including testosterone, in Leydig cells. FSH primarily acts on Sertoli cells to synthesize growth factors that are important for spermatogenesis. In addition, FSH also stimulates Sertoli cells to synthesize aromatase, an enzyme that converts the testosterone produced by Leydig cells to estradiol. The testosterone produced by LH stimulation not only acts locally in the testis, but also negatively feeds back on the hypothalamus and pituitary to reduce the release of GnRH and gonadotropins, thereby indirectly regulating its own synthesis.

There are circadian variations in several hormones relevant to male reproduction. Testosterone exhibits a circadian rhythm in serum concentrations, peaking toward the middle-to-late portion of the light phase in rats (Wilson et al., 1976) and mice (Lucas and Eleftheriou, 1980), likely due to the circadian pattern of release of LH from the anterior pituitary in both rats (Taya and Igarashi, 1974) and mice (Jean-Faucher et al., 1986). There are many enzymes and proteins involved in the synthesis of testosterone by Leydig cells, including: StAR, which transports cholesterol into mitochondria; Cyp11a1, which catalyzes the cleavage of cholesterol to pregnenolone; and Cyp17a1, which is involved in several steps in biosynthesis of testosterone. Interestingly, expression of genes coding for these proteins and enzymes in rat Leydig cells exhibit a circadian rhythm in expression preceding that of the peak in testosterone, all peaking in the middle of the light phase of the light: dark cycle (Baburski et al., 2016).

In a study investigating the role of BMAL1 in male fertility, mice that had BMAL1 knocked out had reduced testosterone levels (Alvarez et al., 2008). Additionally, serum LH concentrations were 3-fold higher in knockout mice compared to control animals, suggesting an impairment of the Leydig cells to produce testosterone in response to LH stimulation. Additionally, after examining several key proteins and enzymes involved in steroidogenesis in the testis of BMAL1 knockout mice, they found that StAR gene and protein expression were significantly reduced, potentially affecting steroidogenesis by decreasing cholesterol uptake into the Leydig cells. Upon further investigation in vitro using a Leydig cell line, they found that BMAL1 induces StAR expression by acting on an upstream promoter.

Androgen Regulation of Behavioral Rhythms

Not only is there circadian regulation of testosterone synthesis in the testis, but testosterone also feeds back on the SCN to regulate gene expression and morphology and thereby modulating circadian rhythms in behavior. Studies that have removal of the gonads (gonadectomy) have revealed that testosterone is an important regulator of circadian rhythms in locomotor behavior. Circulating testosterone mediates behavior by acting locally on androgen receptors (AR) within the SCN. Specifically, AR was colocalized with neurons expressing gastrin-releasing peptide (GRP) within the core region of the SCN (Karatsoreos et al., 2007). GRP-expressing neurons in the SCN are important for the SCN's ability to respond to light, indicating that AR may be involved in regulating light responsiveness in the SCN. Indeed, when light pulses are administered, this causes an increase in the expression of immediate early genes within the SCN. Castration results in reduced immediate early gene expression in response to light pulses given in the subjective night. Replacement with dihydrotestosterone, an AR-specific androgen, restores immediate early gene expression in response to a light pulse given in the dark. Castration of male mice also modulated SCN astroglial abundance in concurrence with irregular expression of the clock genes *Per2* and *Per1* in response to light pulses in the early night and late night, respectively (Karatsoreos et al., 2011). The altered *Per2* expression also resulted in a larger shift in the timing of behavioral rhythms in response to a light pulse, whereas the hormone dihydrotestosterone restored the normal behavioral shift in response to light cues. While the role of astrocytes in the SCN is not well understood, it appears that they may be important for normal SCN function, especially for the regulating response to light cues in the SCN (Karatsoreos et al., 2011).

Gonadectomy has been shown to alter many aspects of locomotor rhythms in constant environmental conditions (i.e. constant darkness), with testosterone replacement rescuing most of these components (Butler et al., 2012). In an early study, castration (thereby removing circulating testosterone) reduces the total amount of wheel running activity, lengthens the free-running period, and shifts the distribution of activity throughout the day, while testosterone replacement restores normal activity patterns (Daan et al., 1975). In addition, a later study showed that gonadectomy induces a more variable onset of activity rhythms, reduces activity levels, and increases the duration of the activity bout (Butler et al., 2012). Interestingly, dihydrotestosterone replacement rescues these measures, indicating an AR-dependent mechanism of androgen regulation of these aspects of locomotor behavior. Model et al. (2015) sought to identify the SCN as the primary site of action in androgen regulation of circadian locomotor rhythms. To directly target the SCN, they gonadectomized mice and stereotactically implanted testosterone propionate (TP) in the SCN. They found that gonadectomy increased free-running period of wheel running activity to an average of 24.48 h, and the SCN TP implant restored the original average free-running period of 24.03 h. Interestingly, they also found that there was a positive correlation with the amount of decrease in free-running period to the amount of AR expression in the SCN. Additionally, they did not observe this same correlation between free-running period and AR expression in other related brain regions, including the preoptic area, bed nucleus of the stria terminalis, and premammillary nucleus. Overall, these studies implicate that androgen action in the SCN, primarily through the hormone receptor AR, is responsible for regulating aspects of circadian locomotor behavior.

Male reproductive behavior has also been shown to exhibit circadian rhythms. Male rats have shorter time (latencies) to first intromission of the penis into the vagina, and ejaculations, and shorter intervals between these events, during the dark than the light phase of the light: dark cycle (Beach and Levinson, 1949; Stefanick, 1983). Interestingly, research using mice that are lacking the clock gene *Bmal1* has connected the core circadian clock to reproductive behavior (Schoeller et al., 2016). Male *Bmal1* knockout

mice are infertile, and when mating behavior was evaluated, researchers found that the males did not mount receptive females. These males also presented with very little anogenital investigation of receptive females, an important behavior for copulation. This behavior is regulated by a complex neural circuit, and it was found that two brain regions involved in this circuit, the bed nucleus of the stria terminalis and medial preoptic area, were both significantly less active in the knockout males compared to wild-type males. While it is clear that the circadian timekeeping system is involved in regulating male reproductive behavior, there are still many details that remain to be elucidated.

Conclusion

Rhythmic expression of core clock genes and proteins has now been observed in rat, mouse, and hamster testes. Additionally, there is also rhythmic expression of these genes and proteins in additional male reproductive tissues, including the epididymis and prostate gland. Furthermore, there is also rhythmic regulation of testosterone production, as well as enzymes and proteins essential for the production of testosterone. Finally, there are rhythms in sexual behavior that are controlled, in part, by clock genes and testosterone. However, the role of the rhythmic expression of many of these genes and proteins remains to be elucidated. Future work in this field will examine the differential expression of clock genes and proteins across different ages of animals, as well as different tissues. Moreover, future work will identify functions for the expression of clock genes and proteins in the male reproductive tract.

Circannual Rhythms

Vinod Kumar and Ila Mishra, University of Delhi, Delhi, India

© 2018 Elsevier Inc. All rights reserved.

Glossary

Amplitude Difference of maximum or minimum from the mean value of a biological oscillation.

Biological rhythm Repeated cycles of a biological function at relatively stable interval.

Circadian rhythm Endogenous biological rhythm with period length of about 24 h.

Circannual rhythm Endogenous biological rhythm with period length of about 1 year.

Clock gene Gene involved in the transcription-translation feedback loop producing near 24 h time.

Free-running rhythm Endogenous rhythm repeats with its natural period under constant conditions.

Free-running period The time interval between consecutive recurrences of the phase marker (e.g., the time of peak or trough) of a free-running rhythm.

Phase An instantaneous point (particular reference point) within the biological rhythm (e.g., onset, mid point or end of activity).

Period The time interval after which a particular phase recurs during the complete biological rhythm.

Entrainment The process which enables endogenous rhythm to assume the period length of the external (environmental) periodicity, e.g., 24 h light-dark cycle or annual changes in the photoperiod cycle.

Synchronization The state in which endogenous and exogenous (environmental) periodicities assume same period length; i.e., both run with same frequency.

Introduction

Circannual rhythms (Latin: *circa* = about; *annum* = year) are endogenously generated oscillations in biological processes with period length of approximately 1 year (12 months) and time changes in the physiology and behavior within each year in long-lived animals. Corresponding to this are circadian rhythms (Latin: *circa* = about; *diem* = day), which are endogenously generated biological functions with period length of approximately 24 h time changes within each day. Among animals, there are many different examples of circannual rhythms; the most notable ones include the insect pupation rhythms, animal migration patterns, pelage growth, hibernation, reproduction and molt cycles. Hence, circannual rhythms are adaptive, and have been evolved to ensure the success of the long-term biological functions, since mistiming of these with the seasonal world will have serious fitness consequences. For example, organisms reproduce during the period of optimal food availability, which is directly responsible for the offspring survival. The life-span of Siberian chipmunks (*Eutamias sibirium*) is affected by their ability and inability to undergo hibernation: those who undergo hibernation cycles live about 11 years, and those failing to do so, live a reduced life-span of about 3 years (Kondo et al., 2006). Overall, circannual timing mechanisms appear to be universal. As we know now that humans themselves are no exception; we are far more a seasonal species than has previously been assumed (Stevenson et al., 2015). Studies have also revealed that basic mechanisms of the circannual rhythmicity are present in the primate lineage; the ancestral circannual clocks continue to tick in us in still unexplored ways, and significantly affect contemporary human life (Stevenson et al., 2015; Helm and Lincoln, 2017).

Naturalists have long speculated endogenous timing mechanism on yearly time scale in the control of biological events. At the beginning of eighteenth century, Ferdinand J. A. von Pernau, a pioneer student of bird behavior, suggested that migratory birds were "driven at the proper time by a hidden drive". Early in nineteenth century, Arnold A. Berthold suggested that the emergence from hibernation in spring was due to the action of endogenous timing factors, and not a simple response to the prevailing environmental stimulus. About a century later, William Rowan argued for the involvement of an internal factor, i.e., a physiological rhythm, in migratory birds that breed in the northern hemisphere, and winter around equator or in the southern hemisphere. In 1960, A. B. Misra suggested, "... the internal rhythm, guided and controlled by genetical factors and fixed by natural selection is the supreme governor of recurrent reproductive physiology of the birds". Both, naturalists and farmers have noted timely return of migratory great knots (*Calidris tenuirostris*) year-after-year, and in few instances this record worked as an agricultural calendar (Foster and Kreitzman, 2009).

Most evidence for the existence of endogenous circannual rhythms, as consolidated by experimental demonstrations in several species, are consistent with the hypothesis that annual timing is based on self-sustained circannual clock(s) which interacts with the environmental photoperiodic zeitgeber (German: *zeit* = time, *geber* = giver; Gwinner, 1986; Numata and Helm, 2014). Few taxonomic groups like insects, birds and hibernating mammals, in particular, captured human interest for detailed scientific investigations over the last about six decades, with seminal and extensive works of Eberhard Gwinner and Eric T. Pongelley on birds and mammals, respectively. An early evidence for circannual rhythm in mammals came from golden-mantled ground squirrel

(*Callospermophilus lateralis*), which displayed circannual cycles in hibernation, food consumption and body mass under constant light and ambient temperature conditions (Pengelley and Fisher, 1963). Strong evidence for avian circannual rhythms came from Ebo Gwinner's studies; the rhythms in migratory restlessness (*Zugunruhe*, demonstrated by intense night activity and wing whirring in night migrants) and molt persisted in captivity for 3 years, suggesting an endogenous regulation of annual migration in willow warblers (*Phylloscopus trochilus*; Gwinner, 1986).

Formal Properties, Stability, and Entrainment

Formal Properties

Circannual rhythms are self-sustained endogenously driven biological oscillations that persist with a regular periodicity of about 12 months in the absence of environmental cycles. Hence, a rhythmic process cannot be designated as 'circannual rhythm' unless it has been experimentally observed to persist in the organism under condition that provides no information about its period. Hence, the constant darkness (DD) or constant dim light (dimLL) can be considered as constant environment condition for circannual rhythm demonstration. Also, 24 h light-dark (LD) cycle (e.g., 12 L:12D) with an unchanging photorefraction contains no information about the year, and so it can be considered as a constant condition for circannual rhythms. Circannual rhythms are temperature compensated: cycle lengths do not vary significantly with change in the constant temperature environment. Overall, circannual rhythms share all fundamental properties with those of the circadian rhythms (Gwinner, 1986; Helm and Lincoln, 2017).

Irving Zucker (2001) reviewed annual rhythms in mammals and distinguished them in three categories, types I, II, and III (Fig. 1). Common among short-lived temperate and boreal species, type I rhythms, although with an endogenous component, do not persist beyond 1 cycle under constant conditions; hence, they are contingent on periodic environmental input. Type II circannual rhythms are found in long-lived species like rodents, carnivores, ungulates, bats and primates. These are endogenous and persist with cycle length of ~12 months under constant conditions; hence, they are not contingent on periodic environmental input. Type III rhythms occur almost with regular periodicity in response to the environmental periodicities; hence, these rhythms do not have an endogenous component, e.g., seasonal allergies in reaction to production of pollens. By-and-large, our present discussion includes types I and II rhythms, which are displayed by different groups, particularly in controlling seasonal reproduction.

Stability and Lability

The period length (Greek: tau, τ) of the free-running circannual rhythm deviates from a year, usually shorter than 12 months. Measured as intervals between two successive peaks in testis growth, circannual testicular rhythm in spotted munia (*Lonchura punctulata*) was found to have $\tau = \sim 11$ months under both constant photoperiod, LL or alternate 24 h of LL/DD at $\sim 20^\circ\text{C}$ temperature (Budki et al., 2012). Circannual reproductive rhythm shows period stability in, as evidenced by similar periods in the circannual testicular cycle in spotted munia under LL at 22- and 90-lx light intensities (cf. Budki et al., 2012, 2014; Fig. 2). Similarly, the average body mass in hibernating ground squirrels (*Citellus lateralis*) cycle with $\tau = 11.3$ and 10.9 months under high ($34 \pm 1^\circ\text{C}$) and low ($5 \pm 1^\circ\text{C}$) temperatures, respectively (Gwinner, 1986). Also, Siberian chipmunks (*Eutamias sibiricus*) maintain precise circannual rhythms of core body temperature for up to a decade both in continuous cold and darkness, although with τ ranging from 5 to 13 months, and hibernation period ranging from 2 to 8 months (Kondo et al., 2006). However, circannual cycles can differ between sexes. Whereas male spotted munia cycle with $\tau = \sim 11$ months (see above), females under same light conditions exhibit circannual cycles with relatively large period variations, $\tau = 10\text{--}13$ months (cf. Budki et al., 2012, 2014). Also, male Siberian chipmunks end their hibernation quite early in the spring when there is still sufficient snow cover, but females emerge from hibernaculum much later in the season when food resources become readily available (Florant and Healy, 2012). Furthermore, individuals can exhibit independent circannual phenotypes, as suggested by differences in the period length, hence frequency, between various circannual functions. For example, molt cycles are more frequent and widely scattered in the year than the gonadal cycles in spotted munia under LL (Budki et al., 2012, 2014; Fig. 3).

Entrainment

Circannual rhythms are synchronized (or "entrained") to local time by appropriate phase shifts, and may involve transients. ($\tau = T$; T is cycle length of an environmental *zeitgeber*, e.g., annual LD cycle). The range of entrainment is broader, and so an entraining LD cycle may vary in T from c. 6–15 months, i.e., $\sim 50\%\text{--}30\%$ of τ of the endogenous circannual rhythm (Gwinner, 1986). Apart from T , the light intensity can influence the synchronization, particularly the inter-individual synchrony. LL at 90 lx reduced variation and increased synchrony between circannual cycles of gonadal maturation and molt among individuals of a group of spotted munia, as compared to those in LL at 22 lx (cf. Budki et al., 2012, 2014).

Fig. 1 Schematic representation of the annual reproductive cycle types. Upper 2 panels: Type I rhythms in which environmental photoperiod is the primary zeitgeber in the regulation and synchronization of annual gonadal cycles. (A): Syrian hamsters (*Mesocricetus auratus*) show gonadal recrudescence and regression under long and short days, and spontaneously regrow their testes under prolonged short day exposure; hence they exhibit refractoriness to the inhibitory effects of the short day, SD. (B): Sheep (*Ovis* sp.) shows refractoriness to both, the stimulatory effects of SD as well as inhibitory effects of LD. Hence, there is the recrudescence and spontaneous regression of gonads under SD; converse is true under LD. A photoperiod change is therefore required to break the refractoriness. (C): Type II rhythms are endogenous cycles and persist under constant photoperiod and constant light/darkness. There seems no particular day length requirement to induce the gonadal recrudescence—regression cycle. Drawn based on Zucker (2001).

Circannual Rhythms and Reproduction

Circannual rhythms temporally space out seasonal phenologies in the year such that a species can profitably utilize resources available in its surroundings and survive through the unfavorable conditions, if any. Reproduction, in particular, is timed to occur during the year when feeding resources are optimal and ensure the survival of newborns. This necessitates that physiological processes underlying reproduction (e.g., pair formation, as required; gonadal maturation; mating; incubation/gestation) are initiated, terminated and reinitiated within a specified temporal window in the year, with a great time precision. Hence, species have evolved and are genetically programmed with an endogenous circannual timekeeping system, which in interaction with prevailing environment helps individuals (or population) anticipate the most favorable time in the year. Experimental studies support this. The black caps (*Sylvia atricapilla*) from Cape Verde breed twice and from central Europe breed once a year, and they continue to show two and single circannual cycles in testis maturation, respectively, even when placed under constant artificial 13 h light per day (Helm and Lincoln, 2017). Similar trans-generational persistence of circannual gonadal and molt cycles has been demonstrated in equatorial African stonechats (*Saxicola torquatus axillaris*): both hand-raised and their offspring displayed similar circannual cycles under constant photoperiod conditions (Gwinner, 1996). Thus, circannual rhythm generation and photoperiodism (environmental photoperiod times component events of a seasonal process) may not be mutually exclusive and, in fact, might interact closely, albeit in species-specific manner, as per the adaptive needs.

Fig. 2 Circannual reproductive cycles under constant photoperiods. Left panel: circannual cycles in the pupation in Carpet beetles (*Anthrenus verbasci*; 4-stage life cycle holometabolous insect), and in the testicular growth-regression in garden warblers (*Sylvia borin*; an avian migrant) and tropical bat (*Anoura geoffroyi*) under equinox, or near equinox, photoperiod (12L:12D, 12.32L:11.68D). Right panels: circannual gonadal growth-regression cycles in male and female spotted munia (*Lonchura punctulata*) under natural day length (NDL), and under 12L:12D or LL at 22- and 90-lx light intensities. Asterisks indicate the time of peak gonadal growth. Note light intensity dependent modulation of the circannual gonadal cycles in the spotted munia. Drawn based on Gwinner (1986), Heidemann and Bronson (1994), Budki et al. (2012, 2014), and Miyazaki et al. (2014).

Fig. 3 Relationship of molt with reproductive cycle in spotted munia (*Lonchura punctulata*). The time of initiation of wing primaries molt of in the first circannual cycle plotted in relation to peak gonadal size (indicated by time '0' value on x-axis) under natural day length, and equinox photoperiod (12L:12D) or constant light (LL) at 22- and 90-lx intensities. The time scale on x-axis expands for 365 days on each side of '0', with minus (–) and plus (+) signs indicating the onset of molt prior to, and after the peak gonadal response (time 0), respectively. Blue and red circles represent data for individual male and female birds, respectively. Note light intensity dependent effects under 12L:12D and LL. Drawn based on Budki et al. (2012, 2014)

Insects

Most insect species have life cycle shorter than a year, and thus do not seem to be in need of the circannual timing. But, holometabolous insect like carpet beetles (*Anthrenus verbasci*) with 4-stage life cycle of ≥ 2 years utilize circannual timing for seasonal events. Adult beetles emerge, mate and lay eggs from spring to early summers, depending on the climate and nutritional conditions. Under constant temperature and darkness, the pupation and development of *A. verbasci* exhibits a circannual rhythm with $\tau = \sim 40$ weeks in both British and Japanese populations (Miyazaki et al., 2014). The rhythms were temperature compensated, although larvae pupated earlier at high (25°C) and later at low (15°C) temperatures. Light period also affected the circannual pupation rhythm, as shown by a clear rhythm under 12L:12D and complete arrhythmicity under 15L: 9D (Miyazaki et al., 2014). Similarly, circannual cycles persist in oviposition and larvae pupation over 5 years in ants (*Formica aquilina*, *F. polyctena*), although with huge individual differences in the cycle length, to some extent affected by the prevailing photoperiod and temperature (Miyazaki et al., 2014).

Birds

Circannual rhythms have been demonstrated in gonad development and “postnuptial” molt in several birds, with pioneering investigations of Ebo Gwinner (see Gwinner, 1986). The longest record of circannual cycles of gonad development and molt over 15 years is from African stonechats under 12.25L:11.75D (see Gwinner, 1996). In the most constant year-round environment of equatorial rainforest, chestnut-winged babblers (*Stachyris erythroptera*) and little spider hunter (*Arachnothera longirostris*) show circannual cycles in breeding and molt with a period length of about 9 months (see Gwinner, 1986). Similarly, subtropical spotted munia (*Lonchura punctulata*) show recurrent circannual cycles in gonadal maturation and molt under different light conditions, including LD cycles and LL (Figs. 2 and 3; Budki et al., 2014). A circannual cycle in reproduction is not the feature restricted to equatorial or tropical species. Temperate species also show circannual cycles in gonadal maturation. European starlings (*Sturnus vulgaris*) show recurrent testicular cycles under 12L:12D (Gwinner, 1986). Similarly, migratory dark-eyed juncos (*Junco hyemalis*) show circannual cycles in both testes and migratory phenotypes (e.g. spring pre-migratory body fattening, Zugunruhe) under dim LL of 1–3 lx (Rani and Kumar, 2013).

Mammals

Circannual rhythms have been shown in short and long day breeding mammals, such as sheep (*Ovis* sp.), sika deer (*Cervus nippon*), bats (*Antrozous pallidus*, *Anoura geoffroyi*, *Phyllostomus hastatus*) and rodents (Syrian hamster, *Mesocricetus auratus*; Siberian hamster, *Phodopus sungorus*; European hamster, *Cricetus cricetus*) (Heidemann and Bronson, 1994; Lincoln and Hazlerigg, 2014; Numata and Helm, 2014; Helm and Lincoln, 2017; Figs. 1 and 2), although with subtle differences in features, as compared to those found in birds (see above). Sheep, a short day breeder, undergoes circannual cycles of reproduction (gonadal maturation, luteinizing hormone and prolactin secretions) and molt under constant conditions. Sika deers display circannual cycles in the testicular growth, antler replacement, and coat color and molt under constant photoperiods. Circannual rhythms persist in gonad development cycle and pelage color in rodents, including squirrels, hamsters and mice. Circannual cycles of body mass and estrous freerun golden-mantled ground squirrels under $T = 23, 24$ or 25 h LD cycles, in which they synchronized circadian activity rhythms (Zucker, 2001). Similarly, small vesper mice (*Calomys laucha*), a south American rodent, show circannual cycles in pelage color (orange and light summer pelage, and gray and dark winter pelage) under 12L:12D at 22°C (Camargo et al., 2006).

Circannual rhythms have also been suggested operating in biological functions of humans including the reproduction-associated measures, albeit with inconsistencies between findings. Human birth pulses can fluctuate seasonally with an amplitude of about 10%, which is substantial for a species that effectively performs physiological functions under conditions of an eternal summer maintained within the body 37°C (the core body temperature). The amplitude of seasonal rhythms indicated by the timing of maxima can vary with the latitude, suggesting an underlying physiological regulatory mechanism. The pattern of birth pulses appears to have a longer-term relevance because birth-month correlates with life-long impacts on health, including the likelihood of general, psychiatric or neurological illnesses (Stevenson et al., 2015). An 8-year study of the semen analysis from human volunteers found a statistically significant high-amplitude seasonal variation in the sperm count (not ejaculate volume or percent motile sperms), with highest values in late winter and early spring, and lowest values in the late summer (Saint Pol et al., 1989). Furthermore, both the presence and absence of circannual cycles in circulating testosterone levels have been reported in humans (Smith et al., 2013).

Inter- and Intra-Specific Differences

Among species that do show circannual rhythms, all individuals may not show them, and the cycle length can also vary considerably from 12 months even among individuals that show them. Circannual cycles of gonadal maturation and pelage growth or molt can also differ between sexes. Unlike males, female European starlings lack a robust circannual response, and exhibit less clear rhythms with larger variations in the period and frequency of cycles in plasma LH and prolactin levels (Dawson, 2007). Also, circannual ovarian cycles, as shown by follicular maturation, were less pronounced and had larger variations than the testes in spotted munia (Budki et al., 2012; Fig. 2). These suggest sex-dependent timing strategies, with females appearing to share a greater role in defining

the reproductive season in relation with the environment. Different circannual rhythms can vary within an individual: cycles of “postnuptial” molt get out of phase with the gonadal cycle in spotted munia under LL (Fig. 3; Rani and Kumar, 2013).

Circannual Rhythms and Photoperiodism

In nature, various environmental factors, most reliably the changes in photoperiod, synchronize the timing of circannual clock-mediated physiological processes to occur at a particular time during the year, which is best-suited for survival and adaptability. Hence, organism-specific experimental strategies are manifested in circannual cycles. Circannual cycles freerun in several birds (e.g., spotted munia, dark-eyed juncos) under constant photoperiod or LL, but these require a photoperiod change at a particular phase of the cycle to express in many mammals (e.g., sheep, sika deer, hamsters; Fig. 1). European starlings held under constant photoperiods exceeding 12.5L:11.5D or < 11.5L:12.5D fail to exhibit circannual cycles. Furthermore, artificial simulations of annual photoperiod variation can entrain circannual cycles to periods as short as 4 months and as long as 2 years. Photoperiodic entrainment can also vary between populations. For example, post juvenile molt in the long distance migrant population of Siberian stonechats (*Saxicola torquata maura*) is earlier and faster than in the short distance migrating European stonechats (*S.t. rubicola*); molt is further slower and late in the nonmigrating east-African stonechats (*S.t. axillaris*).

Circannual Timing: Putative Mechanisms

Va. Endogenous clocks: Several line of evidence show that circadian pacemaker system (CPS) is not involved in the circannual rhythm generation. The ablation of the suprachiasmatic nuclei (SCN), which contains CPS in mammals, eliminates circadian rhythms in activity, but not the circannual cycles of body mass and reproductive phenotypes in golden-mantled ground squirrels (Zucker, 2001). Sika deers show circannual cycles under LD cycles (4.94 L:4.94D, 6L:6D, 8L:8D and 21L:21D) which fail to induce the circadian entrainment (Helm and Lincoln, 2017). Similarly, spotted munia show free-running circannual rhythms in gonad development and molt under LL which induces circadian rhythm disruption both at the behavioral and circadian gene transcriptional levels (Budki et al., 2014; our unpublished data). Thus, a biological year is not defined by 360-odd circadian days. CPS could still have modulatory role in the annual timing, as shown by alteration in the long-term timing and structure of circannual hibernation cycle in SCN ablated squirrels (see Zucker, 2001). Daily oscillations of core clock genes (*PERIODS*, *PERs*; *CRYPTOCHROMES*, *CRYs*; *BRAIN AND MUSCLE ARNT LIKE PROTEIN 1*, *BMAL1*; *CIRCADIAN LOCOMOTOR OUTPUT CYCLES KAPUT*, *CLOCK*) also show alterations between short and long days, and between seasonal states in photoperiodic birds (Cassone and Yoshimura, 2015; Singh et al., 2015).

Thyroid Hormone (TH) Responsive Hypothalamic Pathways

Highly conserved TH-responsive molecular mechanism mediates the photostimulation of gonadal growth and development in both short- and long-day species (Cassone and Yoshimura, 2015; Fig. 4). It begins with concurrent activation of the *EYA3* (eye absent 3) and *TSH-beta* (thyroid stimulating hormone-beta) genes in pars tuberalis (PT) thyrotrophs in response to stimulatory photoperiod, as perceived by brain photopigments (e.g., neuropsin) in birds and by CPS-controlled duration of night melatonin secretion in mammals (Fig. 4). TSH (product of *TSH-alpha* and *TSH-beta*) from PT thyrotrophs activates and suppresses transcription of genes coding for type 2 and 3 deiodinases (*DIO2* and *DIO3*), respectively, in tanycytes (ependymal cells lining the third ventricle). *DIO2* and *DIO3* mediate conversion of thyroxine (T4) into biologically active T3 (tri-iodothyronine) and inactive rT3 (reverse T3) forms, respectively. T3 regulates GnRH (gonadotropin releasing hormone) synthesis and/or release from the preoptic area into median eminence, and consequently the pituitary gonadotropins secretion and gonadal response (Fig. 4). TH signaling also plays a role in the seasonal timing of hibernation in golden-mantled ground squirrels. Recently, chromogranin (CHGA, a hormone-packaging molecule) has been identified as the robust marker of short photoperiod in sheep. Wood et al. (2015) report binary switching of PT thyrotrophs: they exist in CHGA+ form under short-day breeding state, TSH-beta/*EYA3*+ form under long-day nonbreeding state, and spontaneously switch from TSH-beta/*EYA3*+ to CHGA+ state under the long-day refractory state (Fig. 4). Thus, apart from TH signaling, PT seems to drive long-term circannual cycles with individual cells undergoing recapitulation of the developmental state. It remains to be tested however if TH-responsive mechanism is key to the circannual rhythm generation in a nonphotoperiodic species; our initial studies on spotted munia fail to this, however.

The Other Hypothalamic Nuclei/Candidate Molecules

Recent researches have implicated various other hypothalamic structures and candidate molecules in the circannual timekeeping. For example, ventromedial and lateral hypothalamus (VMH, LH), arcuate nucleus (ARC), paraventricular nucleus (PVN) and dorsomedial hypothalamus (DMH) play roles in the seasonal regulation of feeding and energy balance. In hibernators, ARC regulates body mass cycles, and mediates the torpor; T3 acts in ARC and PVN as a low energy signal during fasting (Florant and Healy, 2012). In chipmunks, hibernation-specific proteins (HP) complex concentration in blood closely correlates with the circannual hibernation rhythm, with down regulation of HP prior to the onset of hibernation (Kondo et al., 2006). VGF (nonacronymic) is

Fig. 4 Mechanisms for seasonal timing of gonad development. Upper half: Changes in the HPG (hypothalamic-pituitary-gonadal) axis involved in the regulation of type I and type II annual reproductive cycles. In type I annual reproductive cycles, the relay of light information in mammals is from the retina via SCN activity-dependent melatonin secretion, while in birds light is perceived through the deep brain photoreceptor photopigments, e.g., neuropsin, OPN5. PT-thyrotroph derived TSH activates DIO2 expression in response to long days in both summer and winter breeders. Although increased synthesis/ release of GnRH (gonadotropins releasing hormone) and pituitary gonadotropins cause gonad development in species that exemplify type II annual reproductive cycles, how is light information decoded and transduced upstream is not well understood, as yet. However, we found no difference in *DIO2* and *DIO3* mRNA expressions in mediobasal hypothalamus of a strong circannual species, the spotted munia (*Lonchura punctulata*; unpubl. Obs.). Up and down arrows indicate high and low expression levels, respectively. Lower half: A proposed model for circannual timekeeping in sheep. Individual pituitary pars tuberalis (PT) thyrotrophs exist in the binary state. The relative proportion of these binary state cells determines the phase of the circannual cycle (breeding: CHGA+, Chromogranin A positive; non-breeding: EYA3+/TSH+, eye absent 3/thyroid stimulating hormone positive). In SD breeding and LD refractory states (left and right panels), there is an increase in the deiodinase type 3 (DIO3) expression in the ependymal cells, the tanycytes lining the 3rd ventricle. DIO3 mediates the conversion of thyroxine (T4) into its inactive form (triiodothyronine, rT3), and hence reduces local concentration of its active, T3. As a consequence, the tanycyte end feet retract, and eliminate the physical barrier for GnRH secretion. In the nonbreeding LD state (middle panel), PT-thyrotroph derived TSH activates DIO2 expression and hence enhances T3. As a consequence occur the neuronal remodeling and the encasement of neuronal synapses by tanycyte end feet. These suggest a physical mechanism for the control of GnRH secretion, and downstream gonadotropin release and gonadal response. PT thyrotrophs thus operate as a calendar cell, and generate long-term neuroendocrine rhythms in both the hypothalamus and pituitary gland. Schematically drawn based on Cassone and Yoshimura (2015) and Wood et al. (2015).

another most abundantly expressed molecule in the hypothalamus, and involved in the energy balance and reproduction. VGF mRNA is induced in the ARC, in both Syrian and Siberian hamsters transferred from long to short days (Barrett et al., 2005). VGF also plays a role in the synaptic plasticity, and seem important for the reduction of synaptic connectivity in the song control system, as required post-breeding in songbirds and during torpor bouts in hibernating mammals (Schwartz and Andrews, 2013). Hypothalamic VGF might play a role in the seasonal switch from hyperphagic behavior in summer and early fall to the hypophagic behavior during the hibernation (Schwartz and Andrews, 2013). In hibernators like thirteen-lined ground squirrels (*Spermophilus tridecemlineatus*), brain VGF expression is increased in October when there is decreased food consumption and increased white adipose stores, and is the onset of shallow torpor bouts (Schwartz and Andrews, 2013).

Emerging Concepts in Circannual Rhythm Research

At the present time, three concepts seem emerging to explain the annual timing. Recent studies on seasonally breeding sheep suggest pituitary PT as the putative site of the circannual rhythm generation (see above). It remains inconclusive if PT acts as the circannual pacemaker, as does the SCN as the circadian pacemaker; the autonomous switching in PT genes may be governed by still an undefined structure/ mechanism. A second concept revolves around the involvement of circadian timing in seasonal processes, at least in photoperiodic species with a robust self-sustained circadian system. This is supported by recent demonstrations of alteration in the expression level, 24 h expression patterns, and 24 h rhythm waveforms (phase, amplitude) in the hypothalamic mRNA oscillations of core clock genes, and of genes involved in the photoperiodic transduction and neurosteroid dependent processes, in parallel with seasonal changes in the physiology and behavior (e.g., reproduction, migration) in migratory blackheaded buntings (*Emberiza melanocephala*; Singh et al., 2015; Mishra et al., 2017). The third concept underlies that circannual cycles are generated by tissue-autonomous histogenesis, which includes the formation of a complex tissue system from undifferentiated cells, as a result of complex developmental processes such as the cell differentiation, tissue remodeling and feedback signaling between and within tissues (Lincoln and Hazlerigg, 2014). Exclusive demonstration for this is still lacking, however.

Perhaps an answer to the question whether annual timing of temporally spaced seasonal behaviors has a common regulatory site, as is the SCN for the regulation of many daily responses, is key to finding the circannual pacemaker. Else, circannual timing might include independent phase-related seasonal processes? Perhaps, uncovering genes and protein pathways underlying the induction and maintenance, and the termination and reinitiation of seasonal response (e.g., molecular genetics of migratory or seasonally breeding birds) might enable us to understand the mechanism of circannual rhythm generation. Current advances in molecular tools, and its usage in studying the non-model organisms have greatly improved and should enhance our ability to understand where and how are the circannual rhythms generated.

Introduction

The formation of spermatozoa is an intricate process maintained through a complex network of both peripheral and local interactions. Several testicular cells are involved in this process that occurs in the seminiferous tubules and depends of a close interaction between those cells, particularly germ cells and Sertoli cells (SCs). Germ cells develop in a particular environment, isolated and protected by the blood-testis barrier (BTB) that is formed by adjacent SCs. The BTB divides the seminiferous epithelium into two compartments, the basolateral and the adluminal, which allow the developing germ cells to uptake different nutrients and energetic substrates. Germ cells at the basolateral compartment have access to substrates present in peripheral circulation, whilst secluded germ cells at adluminal compartment are completely dependent on metabolites resulting from SCs secretion (Rato et al., 2012). This partly explains why the metabolic phenotype of germ cells varies according to their differentiation state.

Spermatogenesis is a high-energy dependent process in which germ cells are constantly nourished to meet the energy requirements for several processes, including biosynthetic activities, otherwise, they degenerate. This topic was overlooked for a long time, but the relevance of testicular cells metabolism has gained interest from basic to clinical professionals due to its relevance to male fertility. The link between metabolism and reproductive function is extremely susceptible to insults, such as those promoted by external factors or diseases. It is generally accepted that both, our lifestyle and the surrounding environment, play a key role on that link. So there is an urgent need to find new possibilities that may reduce or even counteract the deleterious effects of those threats to the reproductive health of males. In this context, testicular metabolism has emerged as a possible site for therapeutic intervention. Indeed, cell metabolism has become a subject of renewal interest in the last years, possibly aided by the novel biochemical and molecular tools that allow an in-depth study of the metabolic pathways in cells and organs. It is expected that in the next years the emerging field of “omics” provide new opportunities and advances in our understanding of the testicular metabolic pathways and how they can be manipulated at the clinical level. In this chapter, we will present a brief overview of the main metabolic pathways occurring in the testis, with special emphasis on the metabolic cooperation established between SCs and germ cells, as well as the main pathways fueling sperm metabolism. Finally, it will be also discussed how the metabolic cues induced by metabolic diseases change the energetics of testicular tissue and may compromise male fertility.

Metabolic Cooperation in Testis Is a Key Event for a Normal Spermatogenesis

In the seminiferous tubules it occurs a cellular metabolic cooperation between SCs and germ cells. The latter are highly dependent on the physical and nutritional support of the former. SCs, also known as “nurse” cells, do not follow the same metabolic pattern of most normal cells and only use a minor part of glucose to face their own energy requirements. The majority of this sugar is converted to lactate and delivered to the developing germ cells. This metabolic cooperation is vital for male fertility and depends on the proper functioning of several metabolic pathways controlled by a complex network of hormones and endogenous factors that are mostly secreted by germ cells. Adjacent SCs are responsible for the formation of the blood-testis barrier (BTB), dividing the seminiferous epithelium into the basal and adluminal compartments, and allowing the development of germ cells in an adequate environment. The pH and ionic composition of the tubular fluid, as well the selective passage of substrates, is under the control of SCs, mainly through specific solute carriers located at the surface of plasma membrane. For instance, solute carrier family 2, also known as glucose transporters (GLUTs) is a family consisting of 14 members that mediate the facilitated diffusion of glucose. Of these members, SCs express glucose transporter 1 (GLUT1), glucose transporter 2 (GLUT2), glucose transporter 3 (GLUT3) and glucose transporter 4 (GLUT4), which are mainly involved in the uptake of extracellular glucose. Glucose transporter 8 (GLUT8) is also present in SCs but is only involved in the transport of glucose between cellular compartments.

Once inside the cells, glucose undergoes a series of multistep reactions catalyzed by several enzymes where phosphofructokinase (PFK) catalyzes a rate-limiting reaction converting fructose-6-phosphate to fructose-1,6-bisphosphate in an irreversible manner. The final product of glycolysis is pyruvate, which may follow three different pathways: (1) being converted into alanine, by alanine aminotransferase (ALT); (2) it can be converted into acetyl-CoA in mitochondria and enter the Krebs cycle; or (3) it can be converted to lactate by lactate dehydrogenase (LDH), with a concomitant oxidation of nicotinamide adenine dinucleotide (NADH) into NAD^+ . The resulting lactate is then preferentially exported through monocarboxylate transporters (MCTs) to the existing space between SCs and germ cells. From all the 14 members of the MCTs family, monocarboxylate transporter 1 (MCT1) and monocarboxylate transporter 4 (MCT4) are expressed by SCs, where MCT4 mainly acts as lactate exporter due to its low affinity for this metabolite (Fig. 1) (Oliveira et al., 2015). Not all germ cells are dependent on lactate supply by SCs. In fact, spermatogenic cells express several glycolytic enzymes, but only those located closest to the basement membrane of the seminiferous tubules are

Fig. 1 Schematic illustration of the metabolic cooperation between the Sertoli cells (SCs) and developing germ cells. The SCs consume several substrates, such as glucose, lactate and fatty acids. Though glycolytic pathway, glucose is metabolized into pyruvate which can (i) be converted into Acetyl-CoA, which can enter the Krebs cycle; (ii) be converted into alanine via alanine transaminase or (iii) be converted into lactate via lactate dehydrogenase (LDH). The extracellular lactate and pyruvate are transported through the family of proton-linked plasma membrane transporters known as the monocarboxylate transporters (MCTs), while glucose is imported via the family of membrane proteins called glucose transporters (GLUTs). SCs can maintain their viability in the complete absence of glucose, still producing energy and lactate via β -oxidation of fatty acids. SCs also accumulate glycogen that can be readily hydrolyzed when glucose is not available and/or when its metabolism is deficient. In the lumen of the seminiferous tubules spermatozoa rely majorly in the glucose and fructose available in the fluid. *GLUT1*, glucose transporter 1; *GLUT2*, glucose transporter 2; *GLUT3*, glucose transporter 3; *ALT*, alanine aminotransferase; *LDH*, Lactate dehydrogenase; *MCT4*, monocarboxylate transporter 4; *PPP*, pentose phosphate pathway.

able to use glucose, whereas germ cells located beyond BTB cannot metabolize this sugar. For instance, pachytene spermatocytes rely on the supply of lactate from SCs. Lactate is also the preferred substrate of early spermatids and the production of energy in those cells is more efficient in the presence of high concentrations of this metabolite, illustrating their lower glycolytic potential (Bajpai et al., 1998). Despite the presence of all molecular machinery necessary for the metabolism of glucose, the high dependency of the secluded germ cells in lactate may be caused by inefficient oxygen diffusion through the epithelium but this hypothesis needs further investigation.

Lactate is more than an energy substrate to germ cells. It stimulates the synthesis of ribonucleic acid and protein in developing germ cells, but also helps to promote the activation of alternative metabolic pathways, such as gluconeogenesis and the pentose-phosphate pathway (PPP) since may be “recycled” to glucose-6-phosphate. In addition, lactate is a relevant factor for the survival of germ cells since the administration of exogenous lactate in adult cryptorchid rat testis was shown to suppress the loss of spermatocytes and spermatids (Courtens and Ploen, 1999). This was later observed in humans, since the treatment of seminiferous tubules with lactate prevented the apoptosis of germ cells, especially spermatocytes and spermatids (Erkkila et al., 2002).

Besides lactate, acetate is also produced at high rates by SCs. Acetate is a crossroad metabolite and is converted to acetyl-CoA either in the cytoplasm or in mitochondrial matrix by acetyl-CoA synthase. It is a central metabolite for the synthesis of cholesterol and other precursors of lipids. Thus, it has been proposed that acetate is essential for the maintenance of the high rate of lipids synthesis and the intense remodeling of the germ cells’ membranes during their development (Alves et al., 2012). However, lipids are also used by mature SCs as an energy substrate. These cells degrade residual bodies, as well as phagocytized apoptotic spermatogenic cells, which enables the recycling of lipids to produce ATP (Fig. 1). β -oxidation of fatty acids is the preferred pathway to guarantee their own energy requirements, which may explain why SCs maintain the synthesis of ATP and their viability even when glucose is absent (Xiong et al., 2009). However, the metabolism of aminoacids must not be excluded, since the enzyme branched-chain aminoacid aminotransferase, responsible for the conversion of the branched-chain aminoacids (such as valine, leucine, and isoleucine) to the corresponding branched-chain acids was identified in SCs (Kaiser et al., 2005). Apart from the role of these alternative substrates in the metabolism of SCs, endogenous substrates such as glycogen may also have huge relevance in the maintenance of SCs high glycolytic activity.

Metabolic Requirements of Spermatozoa

After being released in the lumen of the seminiferous tubules, spermatozoa become independent from the nutritional support of SCs. They will begin their journey towards the epididymis and pass through maturation in a series of events occurring in a synchronized manner. As they pass through epididymis, spermatozoa must fuel all molecular events taking place either in the cytoplasm as in the surface of the membrane. Even within the female reproductive tract, spermatozoa must ensure efficient energy production to successfully achieve acrosome reaction and capacitation, otherwise, fertilization will not occur. Unlike secluded germ cells, spermatozoa are able to maintain their energy levels through glycolysis, but also through oxidative phosphorylation (OXPHOS) (Fig. 2). In fact, both processes may occur independently or in combination depending on the surrounding environment. This is possible due to the highly specialized structure of spermatozoa, which allows the compartmentalization of energy production. The ATP generated through OXPHOS occurs in mitochondria, while the synthesis of ATP through glycolysis takes place in the head and the fibrous sheath, due to the absence of respiratory enzymes. Several glycolytic enzymes, such as hexokinase, PFK, LDH and glyceraldehyde-3-phosphate dehydrogenase (GAPD) are present in these segments of spermatozoa. The preferred substrates of spermatozoa are glucose and fructose. These hexoses are taken up through GLUTs present along the plasma membrane. GLUT1 and GLUT2 are expressed in the acrosomal region and in both main and end pieces of the flagellum, while GLUT3 has been described in the mid-piece of human spermatozoa (Angulo et al., 1998). Other members, such as GLUT8 can be found in the acrosomal region, post-acrosomal region, and flagellum. The presence of glucose transporter 9 (GLUT9) was reported in the acrosome, midpiece and main piece of the mouse sperm. It is interesting to observe that all GLUTs isoforms are mainly distributed in the head, particularly in the acrosomal region and in several parts of the tail (Kim and Moley, 2007), showing that those events preceded by oocyte fertilization may depend on the glucose-derived ATP. Indeed, glucose alone is sufficient to support the protein tyrosine phosphorylation events associated with spermatozoa capacitation. From all GLUTs isoforms expressed by spermatozoa, glucose transporter 5, is the one with higher affinity for fructose and is confined to the subequatorial region of the spermatozoa, midpiece and main piece. Glucose taken up from the seminal fluid is metabolized originating two molecules of ATP, pyruvate, and nicotinamide adenine nucleotide (NADH). Pyruvate is then further metabolized to produce lactate, which can also be used as energetic substrate. In the same way, fructose is internalized and phosphorylated by fructokinase to fructose-1-phosphate, which undergoes hydrolysis by fructose-1-phosphate aldolase yielding dihydroxyacetone phosphate (DHAP) and glyceraldehyde. DHAP is converted to glyceraldehyde-3-phosphate by triosephosphate isomerase or glyceraldehyde kinase. From this point, intermediates of the glycolytic pathway are obtained and can finally be converted to pyruvate and lactate for energy production. It is interesting that spermatozoa possess all molecular machinery involved in energy metabolism to support the sliding flagellar movements under oxygen deprivation. However, the use of metabolic substrates for ATP production may vary between species and consequently may dictate the main pathway required for ATP synthesis. When the availability of glycolytic substrates is scarce, the energy production is ensured by mitochondria. It is known that the most efficient energy process occurs under aerobic conditions and in these conditions pyruvate is irreversibly converted to acetyl-CoA by pyruvate dehydrogenase, which then enters the Krebs cycle to combine with oxaloacetate (OAA). OAA is then further oxidized to reduce NAD^+ and the complex II prosthetic group flavin adenine dinucleotide generating carbon dioxide. The oxidation of these substrates is coupled with the phosphorylation of adenosine diphosphate via the mitochondrial electron transport chain, with the subsequent production of ATP. These are the two main metabolic pathways in sperm metabolism, however, an exacerbated or deficient mitochondrial function is often associated with the production of reactive oxygen species (ROS). ROS are extremely dangerous for the viability of spermatozoa and their overproduction have been recognized as a major cause of male infertility. Spermatozoa are poor on antioxidant defenses, so these cells are dependent on the surrounding antioxidant systems.

Fig. 2 Schematic illustration of the main metabolic pathways involved in the sperm functions. These cells rely on glucose and fructose available in the fluid of reproductive male tract, however they can also to obtain energy by using lactate, pyruvate and other substrates (e.g. citrate, fatty acids and aminoacids). The major pathways of sperm metabolism are glycolysis and oxidative phosphorylation which are essential to fuel all energy requirements of the maturation-associated events. In the reproductive female tract sperm rely in high concentration of glucose, lactate and pyruvate. Glycolysis is the predominant pathway for fertilization, since is used for sperm capacitation and during acrosome reaction, but this may vary between species. Glucose is also important to the pentose-phosphate pathway that is involved in the sperm entry into the oocyte. When substrates for glycolysis are absent, sperm use other substrates to obtain energy through oxidative phosphorylation. *PPP*, pentose phosphate pathway.

When other energy sources are absent, spermatozoa may also use intracellular lipid reserves. Acyl ester bonds of plasmalogen are broken during endogenous respiration resulting “in the release” of fatty acids, which can then be used as a substrate for endogenous respiration (Misro and Ramya, 2012). Glycerol can also be used by spermatozoa and may be converted to fructose and then metabolized via fructolysis. Sperm is also able to oxidize aminoacids. Another pathway that is often used by sperm during fertilization is PPP. Indeed, this is consistent with the increased activity of the glucose-6-phosphate dehydrogenase (G-6-PD) observed in human spermatozoa. G-6-PD is a rate-limiting enzyme essential for the production of reducing equivalents in the form of nicotinamide adenine dinucleotide phosphate (NADPH), which is involved in the activation of NADPH-oxidase. NADPH-oxidase produces radical species, which at low levels promote sperm capacitation, a process that occurs in the female reproductive tract (Travis et al., 2001). Interestingly, the oviductal fluid is highly rich in pyruvate and lactate, which are commonly used as energy substrates by mammalian spermatozoa. In fact, these metabolites may serve as a link between glycolysis and OXPHOS. As aforementioned, lactate derives from the enzymatic reduction of pyruvate by LDH with a concomitant production of NAD^+ . Under anaerobic conditions, this reaction regenerates cytosolic NAD^+ necessary for the progress of the glycolytic pathway. Cytosolic lactate can also be transported into mitochondria of spermatozoa by the mitochondrial lactate carrier, where the presence of the specific isoform of lactate dehydrogenase C reoxidizes lactate to pyruvate in the mitochondrial matrix.

Finally, it is interesting to note that sperm accumulates glycogen and has measurable activities of glycogen synthase and glycogen phosphorylase. However, the real impact of glycogen in the metabolism of spermatozoa needs to be fully explored (Ballester et al., 2000). Mammalian spermatozoa are able to use a variety of substrates allowing energy production independently from mitochondrial activity, thus allowing fertilization possible under divergent conditions.

Metabolic Cues and Male (in)Fertility: From Basic Research to Clinical Considerations

There has never been a greater need to understand the real relevance of testicular metabolism to male reproductive function. This process is complex and any dysregulation in metabolic homeostasis may negatively impact reproductive performance (Rato et al., 2012). Such effects are in part mediated by the endocrine system, which compromises testicular signaling pathways, especially those related to the metabolic cooperation occurring in the seminiferous epithelium. Even a subtle alteration in the consumption of substrates and/or in the production of metabolites may result in a deleterious effect for male fertility. This is alarming considering the epidemic numbers of men suffering from metabolic diseases and it may be expected a decline in male fertility in the upcoming years. Male fertility is extremely susceptible to external insults or diseases and policymakers and health authorities have recognized it as one of the hidden effects of metabolic diseases, particularly diabetes mellitus (DM) and obesity (Rato et al., 2014).

DM induces large hormonal fluctuations, as well as metabolic imbalance directly affecting the function of mature SCs. Glucose metabolism is altered in insulin-deprived SCs, mainly due to the modulation of GLUT1 and GLUT3 expression. Changes in the uptake of glucose may be reflected in the glycolytic potential of SCs. Indeed, insulin-deprived SCs present decreased lactate production due to downregulation of LDH and MCT4 expression (Oliveira et al., 2012). This was the first report showing how absence of insulin directly modulates SCs metabolism. Apart from insulin dysfunction, DM also induces severe alterations in the synthesis of sex steroids. SCs exposed to doses of testosterone (T) and 17β -estradiol occurring in prediabetic males did not uptake glucose as efficiently as compared to SCs exposed to sex steroids levels observed in type 2 diabetes mellitus (T2DM) (Rato et al., 2015). These findings suggest that alterations of T levels induced by progressive stages of DM alters the metabolism of SCs. Importantly, it was clearly evidenced that the most remarkable metabolic alterations of the SCs were concurrent with the severity degree of the disease. Although the testicular dysfunctions associated with DM go beyond the inhibition of sex steroid synthesis, this may be a key mechanism by which DM affects male fertility. There has been an increasing interest in what regards to the development of a possible strategy to counteract the deleterious effects of DM in these metabolic pathways. Indeed, anti-diabetic drugs, such as metformin (Alves et al., 2014) and pioglitazone (Meneses et al., 2016), are able to increase the glycolytic efficiency of human SCs, providing new evidence of how those drugs can be suitable for male diabetics in order to sustain the nutritional control of spermatogenesis.

Apart from the in vitro approaches, in vivo evidence explored how progressive stages of DM impact testicular metabolism. Prediabetes induced by overconsumption of a high-energy diet increased testicular glycolytic activity and the expression of all key intermediates of this pathway was upregulated, even those involved in the production of lactate such as LDH and MCT4. This evidence came from a prediabetic animal model and shows that testicular metabolism is vulnerable to the effects of the prodromal stage of DM (Rato et al., 2013). Nonetheless, the high glycolytic flux seems to be accompanied by a pro-oxidant environment, where the function of the axis composed by peroxisome proliferator-activated receptor gamma coactivator 1- α (PGC1- α) and sirtuin 3 (SIRT3) is compromised (Rato et al., 2014). PGC1- α and SIRT3 are nuclear-encoded proteins with a key role in the maintenance of mitochondrial function, as well in the activation of antioxidant defenses. Together with the disrupted PGC1- α /SIRT3 axis, a dysregulation of mitochondrial respiration was noted being responsible for a decrease in testicular ATP content. So the hormonal and metabolic fluctuations occurred in the initial stages of DM development compromises normal testicular bioenergetics with the development of a deleterious pro-oxidative environment (Rato et al., 2014). However, as DM progresses to T2DM some of these alterations, especially in the testicular metabolism, tend to become more pronounced. In a T2DM animal model, testicular glycolytic flux is severely compromised as observed by the decreased lactate content and these alterations were associated with a remarkable decrease of sperm quality (Rato et al., 2015).

Similar results have also been observed in diabetic men. Recently the metabolic profile of testicular biopsies from type 1 diabetes mellitus (T1DM) men was established (Alves et al., 2015). The testicular tissue of those individuals showed a decreased content of

both lactate and alanine, which may be caused by impaired uptake of glucose, when compared with normoglycemic men. The expression of LDH and ALT was found to be decreased in the testes of these individuals, contributing to the lower testicular lactate content (Alves et al., 2015). Importantly, the decreased protein levels of ALT together with the decreased alanine content suggest that glycolysis-derived pyruvate is probably being redirected into mitochondria. These findings are consistent with the low intratesticular levels of citrate, an intermediate of the Krebs cycle (Alves et al., 2015). Until now there has never been a detailed study exploring the testicular metabolic profile of T1DM men and thus, that study opened some new insights into the molecular mechanism by which DM promotes subfertility/infertility in humans.

Concluding Remarks and Future Perspectives

The biochemical link established between metabolism and male fertility has been a matter of debate. Male fertility requires an adequate nutritional support of spermatogenesis. In this context, the metabolic cooperation established between SCs and germ cells is pivotal and any dysregulation in this crosstalk may end-up in anomalies in sperm production and thus, male infertility. This process is permanently targeted by hormones and external factors and is vulnerable to stress conditions. Malnutrition behaviors resulting in extreme deprivation of nutrients or excessive energy accumulation must be avoided otherwise the normal flow of testicular metabolic pathways is hampered. Metabolic diseases have also become a matter of great concern since they may be key players in the increased rates of male infertility. The whole hormonal and metabolic imbalance often associated with these diseases disrupts male reproduction at multiple levels, but especially the metabolic cooperation SCs:germ cells. There is no doubt that testicular metabolism is a point of control for spermatogenesis, so exploring these pathways provide new opportunities to allow clarifying how testicular metabolic disruption associated with pathological states end up in infertility. Potential threats for male reproductive health are encountered not only by the modern lifestyle (and consequent development of metabolic diseases such as prediabetes, T2DM, and obesity) but also through permanent exposure to environmental factors, which certainly hamper the metabolism of testicular cells and therefore compromise male fertility. These issues will deserve special attention from researchers and clinicians in the following decades.

Introduction

Nutrition is a primitive need essential for human survival and reproduction. However, the dietary patterns have changed along the years, especially with industrialization and technology that directly or indirectly controlled the food market and promoted a sedentary lifestyle. Over-processed products containing artificial sweeteners, preservatives and refined sugars gained ground over the biological ones. The fact is that over-processed foods are usually produced in a larger scale, making them cheaper and more accessible to everyone. Additionally, multi-million-dollar marketing strategies make those products very attractive, particularly to young people. But not all the alterations of modernization were unfavorable. It also brought increased knowledge and education about nutrition, a higher support by health care systems and the promotion of a healthy lifestyle. But in general, people do not just eat what the body requires to function, they eat bigger portions than they should because eating also gives a sense of relaxation, comfort and pleasure. So, individuals are consuming more and wasting fewer calories. This overeating scenario, together with the lack of physical activity, contributed to the alarming proportions of several diseases worldwide, including diabetes and obesity. On the other hand, there are many countries where food is not so abundant and people are undernourished, which also triggers the development of severe diseases. Even so, according to the World Health Organization (WHO), in many countries overnutrition is now killing more people than undernutrition. However, both malnutrition types contribute to the increasing incidence of diet-related diseases year by year.

In the last decade, there was accumulating evidence for the decline in male fertility potential. In fact, the number of couples seeking for medical assistance to conceive children has increased and in half of those cases the male is the sole cause or contributes to the fertility problem. Nevertheless, there are many undiagnosed cases and we should consider that in some cultures this is still a taboo subject. So, the real numbers of male subfertility and infertility can be even more disturbing. The impact of diet and other daily life activities in male reproductive potential is currently a matter of debate among researchers. In fact, the nutritional status of an individual is of great importance to maintain the well-functioning of the whole body, which may have an impact in the reproductive function. Many minerals, vitamins and other food components obtained through the diet have demonstrated an essential role in processes involved in sperm production and survival. Particularly, there are many dietary compounds with antioxidant properties that are essential for sperm protection from oxidative damages. This chapter will elucidate the influence of diet and lifestyle on male reproduction, unveiling several nutritional factors with a beneficial or negative impact on male fertility.

Nutrition, Lifestyle and Male Reproduction

Modern societies are currently aware of the benefits of having an adequate nutrition and practicing regular physical activity and how these factors can influence important aspects of people's life. Although this so called "healthy lifestyle" may vary among cultures, it has been associated with the prevention of many diseases, which led many people to change their daily habits. However, great part of the population still devalues the importance of having a well-balanced diet. On the other hand, it is difficult to promote a healthier lifestyle when there are so many attractive fast food restaurants to try out. For instance, in the USA there are over 200,000 fast food restaurants with a huge diversity of concepts and meals, leading countless Americans to eat fast food daily. Moreover, millions of vending machines containing soft drinks, sweets and refined foods are available pretty much everywhere, thus reflecting the actual tastes and choices of consumers. The scenario is even most worrying because children and adolescents are the most attracted ones. Generally, people are on a rush, thus making bad food choices, eating too fast, alone and less frequently or even resort to food supplements to save time. This situation usually leads to nutritional deficiencies, whether of one or more nutrients, having negative outcomes for human health. Additionally, there are many jobs with a sedentary nature or that require exposure to high temperatures or toxic compounds during long periods. Furthermore, couples are so focused on their professional careers that are postponing the age to have children and this could be a major obstacle to achieve conception. These current dietary and lifestyle routines make people more susceptible to develop pathological conditions, including male subfertility/infertility. Among the most prevalent diet-related diseases in the world, we can highlight diabetes mellitus, obesity, cardiovascular diseases, cancer and infections, since all these conditions have been linked with a decreased male fertility potential (Dias et al., 2016b). Oxidative stress has been reported as a major contributing factor for the development of those diseases, but it can also be a result of the unhealthy status created by the disease itself. This kind of stress occurs when the production of free radicals overwhelms the ability of inner antioxidant defenses to control them. High levels of oxidative stress are usually found in subfertile and infertile men, thus having a key role on the pathophysiology of male subfertility/infertility. In fact, high levels of free radicals were detected in the semen of 25–40% of infertile men, as well as less amounts of inner antioxidant enzymes than in fertile men (Agarwal et al., 2003). Antioxidant compounds obtained through the diet may be of extreme relevance to restore the reproductive tract antioxidant defense system and avoid fertility dysfunctions induced by oxidative stress.

Oxidative Stress, Antioxidants and Male Fertility

A free radical is a chemical compound with one or more unpaired electron(s) in an outer membrane orbital, which makes it unstable and highly reactive. The term reactive oxygen species (ROS) usually refer to oxygen-containing free radicals, such as superoxide anion ($O_2^{\bullet-}$), hydroxyl ($\bullet OH$) and nitric oxide ($NO^{\bullet}$) radicals, but also to some non-radical oxygen derivatives, including singlet oxygen (1O_2), ozone (O_3), hydrogen peroxide (H_2O_2), peroxyxynitrite anion ($ONOO^-$) and hydrogen hypochlorite ($HClO$). These latter do not contain unpaired electrons but are potentially reactive and can be converted to radical ROS. Cellular endogenous sources of ROS, mostly generated by oxidative phosphorylation in mitochondria or by the immune system, have an essential role in normal cellular processes. In physiological conditions, ROS are involved in the regulation of cell signaling pathways, having the ability to modulate the activity of enzymes, mediate inflammation and control pathogens intrusion. For instance, Sertoli cells, the somatic cells of the testis that are vital for a successful spermatogenesis, require ROS for normal metabolic processes, namely to obtain energy and produce important substrates for germ cells (Dias et al., 2013). Moreover, spermatozoa also need a controlled amount of ROS for essential fertilizing processes such as sperm capacitation, hyperactivation, acrosome reaction and sperm-egg fusion. However, when something disrupts the prooxidant-antioxidant homeostasis in those cells, it promotes an oxidative environment, impairing spermatogenesis and sperm function. Defective spermatozoa (immature or abnormal), high levels of leucocytes present in the ejaculate (leucocytospermia), pathological conditions or other exogenous factors (e.g. smoke, radiation or drugs), are major stimuli for ROS overproduction (Fig. 1). The most common ROS produced in sperm and that can harm their quality are superoxide anion, hydrogen peroxide, nitric oxide and peroxyxynitrite. Proteins, lipids, and DNA are the core targets of ROS since they can capture electrons from them to seek stability. However, this process triggers a cascade of reactions due to the generation of new unstable species that will subsequently try to capture electrons from a nearby molecule as well. These events lead to protein oxidation, lipid peroxidation and/or oxidation of DNA bases, which culminate in severe cellular damages and even cell death. Spermatozoa are quite susceptible to oxidative damages due to their distinctive lipidic membrane and limited intracellular defense system. When ROS attack the polyunsaturated fatty acids (PUFAs)-rich membrane of spermatozoa, lipid radicals are formed, which in the presence of oxygen generate lipid peroxy radicals. Those products contribute to the formation of some dangerous adducts, such as the 4-hydroxynonenal (4-HNE) or thiobarbituric acid reactive substances (TBARS), that stimulate a chain reaction of free radicals' generation usually described as lipid peroxidation. Consequently, spermatozoa membrane loses fluidity, which compromises motility and sperm-egg fusion. ROS can also inactivate key enzymes involved in sperm function by altering their structural conformations. Moreover, ROS-induced damages to mitochondrial and nuclear sperm DNA may end-up in low pregnancy rates, increased birth defects and high offspring morbidity.

Fig. 1 Schematic representation of the oxidative stress-promoting factors in spermatozoa and the respective outcomes for male reproductive function. Nutrition, lifestyle and pathological conditions are among the extrinsic factors promoting oxidative stress in the male reproductive tract. There are also some intrinsic factors such as immature/abnormal spermatozoa and leucocytospermia that may increase ROS production within the male reproductive tract, including in spermatozoa. Superoxide anion radical ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), nitric oxide radical ($NO^{\bullet}$) and peroxyxynitrite anion ($ONOO^-$) are the main types of ROS produced by spermatozoa. ROS overproduction together with the decrease in antioxidant defenses may lead to sperm membrane lipid peroxidation and and/or oxidation of DNA bases. While lipid peroxidation alters the fluidity of spermatozoa membrane, impairing motility and fecundity, DNA oxidation lead to its fragmentation, thus increasing cell death, the number of abnormal spermatozoa and the occurrence of defects/morbidity in the offspring. This culminates in the overall decrease in sperm quality and impairment of male reproductive potential.

Generally, antioxidants are compounds with the ability to scavenge ROS or act as cofactors for the cellular enzymatic antioxidant defenses, thus preventing oxidative-induced damages. To counteract these severe damages, spermatozoa are endowed by an intrinsic antioxidant system that contains a myriad of enzymatic and non-enzymatic components, including superoxide dismutase, catalase, glutathione peroxidase, glutathione transferases, peroxiredoxins and thioredoxins. Still, the amount of those scavenging compounds in spermatozoa cytoplasm is very low. During spermatogenesis, germ cells differentiation is physically protected by the blood-testis barrier formed by Sertoli cells. Chromatin condensation is one of the vital processes occurring during spermatogenesis, in which most of sperm DNA histones are replaced by protamines to obtain a higher compaction and protection. If these events are disrupted and spermatozoa retain more histones than they should, sperm DNA becomes more susceptible to oxidative damages, which is critical since sperm DNA has a low ability for repair. On the other hand, during spermiation, most of spermatozoa cytoplasm and organelles are removed, thus diminishing sperm endogenous defenses. Sometimes, this process is not fully completed and some spermatozoa retain a residual cytoplasmic droplet, which contains enzymes that promote ROS production. Nevertheless, epididymal fluid and seminal plasma possesses a powerful antioxidant system that protect spermatozoa from oxidative stress after being released from the testis. These fluids contain many enzymatic antioxidants, namely superoxide dismutase, catalase and glutathione peroxidase. However, they also contain many non-enzymatic antioxidants that can be obtained through the diet, supporting the key role of nutrition in the control of reproductive fluids composition and antioxidant capacity. Thus, the nutritional state of a man really influences his fertility potential, as well as the frequency of ejaculation and hydration. Some nutritional factors that may influence the antioxidant-pro-oxidant balance in male reproductive tract will be discussed in the following section.

Nutritional Factors Affecting Male Reproductive Function

A well-balanced nutrition includes adequate amounts of vitamins, minerals, protides, carbohydrates and lipids, as well as a limited number of calories to maintain a productive and energetic lifestyle. Depending on the variability of individual tastes and the country-specific dietary habits, variable amounts of antioxidant compounds can be obtained through a healthy diet. But current lifestyle patterns are making this a nearly impossible task, as evidenced by the increasing prevalence of oxidative-related dysfunctions, including in male reproduction. This led to a huge launch of antioxidant-based compounds on the market, which now people incessantly seek as they are claimed as healthy. One of the major concerns is around the market of food supplements that is saturating grocery stores. The consumption of these food supplements to compensate for the lack of dietary antioxidant compounds is becoming a trend. However, they do not require medical prescription and are usually referred to as devoid of side effects. This is a critical issue since the use of non-validated dosages and combinations of several antioxidant compounds, may lead to the depletion of the physiologically required ROS amounts for a normal cellular function, thus doing more harm than good. But for many men that do not want to bring “public” their fertility problems, this self-medicating approach constitutes an appealing alternative. Nevertheless, the consciousness about antioxidant products and their effects in the overall health condition of an individual is increasing. In fact, alterations in nutrition and lifestyle become one of the primary medical recommendations to any treatment, which are commonly called nutritional therapies. For instance, the higher intake of fruits and vegetables, which are natural sources of antioxidants, was associated with the improvement of sperm quality (Gaskins et al., 2012). However, other studies reported that many edible antioxidant-rich plants have the ability to disrupt spermatogenesis and decrease sperm quality, being good candidates for contraceptive purposes but not for subfertility treatments (Dias et al., 2014). There is still a lack of knowledge in this area and many controversial data, due to the high variability of subjects, techniques, compounds, doses and evaluated parameters. Nevertheless, several nutrients and other food components (Table 1) demonstrated a protective effect in spermatozoa by decreasing lipid peroxidation, DNA fragmentation and improving sperm quality. So, the excessive or deficient ingestion of one or more nutrients/food components can affect several processes, such as Sertoli and Leydig cells function, spermatogenesis and sperm quality. The accurate knowledge concerning the recommended dosages of some nutrients to maintain a normal reproductive function is of extreme importance.

Vitamins

Vitamin A comprises a group of related compounds called retinoids, including retinol and beta-carotene, which can be uptake from eggs, sweet potatoes, carrots and pumpkins. Generally, it is essential for vision, immune system and skin health. Due to its characteristic lipid solubility, it is better absorbed when consumed together with fats. The body can store vitamin A in the liver to be used when needed. When it reaches the target sites, it is converted to retinoic acid, so it can bind to its specific receptors. It has been reported that vitamin A participates in certain stages of spermatogenesis by stimulating the transcription of several genes that are involved in meiosis. Moreover, the long-term deprivation of this vitamin in male rats led to the disruption of blood-testis barrier and germ cell aplasia, thus compromising fertility (Morales and Cavicchia, 2002). Higher serum concentrations of retinol were found in men presenting a normal spermogram relative to subfertile ones (oligozoospermia and asthenozoospermia) (Al-Azemi et al., 2009).

Other significant vitamin for male reproduction is vitamin B9 (or folate) that is mainly present in beans, lentils and spinach. This water-soluble vitamin plays an essential role in DNA biosynthesis cycle and repair, cell division and cell growth, which are crucial steps occurring during spermatogenesis. Due to the importance of this micronutrient, a synthetic version of vitamin B9, folic acid,

Table 1 Some nutritional factors obtained from diet that influence male reproductive potential

Nutritional factor	Dietary sources	Major outcomes	References
Vitamin A	Eggs, sweet potatoes, carrots, pumpkins	• Maintains blood-testis-barrier • Avoids germ cell aplasia • Higher concentration in seminal plasma of fertile men	(Morales and Cavicchia, 2002, Al-Azemi et al., 2009)
Vitamin B	Beans, lentils, spinach	• Important for DNA biosynthesis cycle and repair, cell division and cell growth • Decreases the occurrence of aneuploidy in spermatozoa • Improves total sperm count	(Wong et al., 2002, Young et al., 2008)
Vitamin C	Oranges, papaya, strawberries, pineapple, peppers, broccoli, cauliflower	• Sertoli cells express functionally active vitamin C transporters • Lower levels in seminal plasma of infertile men • Improves sperm quality (counts, motility and normal morphology)	(Akmal et al., 2006, Colagar and Marzony, 2009)
Vitamin D	Egg yolks, dairy products, fish	• Immature Sertoli cells and germ cells express vitamin D receptors • Influences intracellular calcium levels • Improves sperm motility	(Jensen et al., 2011)
Vitamin E	Nuts, seeds, green leafy vegetables	• Decreases lipid peroxidation in spermatozoa and seminal plasma • Improves sperm motility • Higher levels in fertile men	(Keskes-Ammar et al., 2003, Al-Azemi et al., 2009)
Vitamin K	Broccoli, cabbage, brussels sprouts	• Promotes testosterone production by Leydig cells	(Oury et al., 2013)
Selenium	Nuts, fish, beef	• Protects spermatozoa from ROS attack • Lower levels in oligospermic and azospermic men • Influences sperm motility and abnormal morphology	(Ahsan et al., 2014)
Zinc	Seafood, beef/lamb meat, wheat	• Cofactor of metalloenzymes involved in DNA transcription, expression of steroid hormone receptors, and protein synthesis • Higher levels in seminal plasma of fertile men • Reduces DNA fragmentation levels	(Colagar et al. 2009; Schmid et al., 2012)
Carnitines	Meat, milk	• Lower levels in azospermic men	(Ahmed et al., 2011)
Coenzyme Q10	Salmon, tuna, beef, nuts, seeds	• Involved in ROS control in spermatozoa • Improves sperm density and motility	(Safarinejad, 2009)
Polyunsaturated fatty acids (PUFAs)	Nuts, fish	• Increase the antioxidant potential of seminal plasma • Improve sperm quality	(Safarinejad et al., 2010)
Catechins	Tea, chocolate, berries	• Modulate Sertoli cells function • Improve sperm viability and motility • Increase male reproductive tract antioxidant potential	(De Amicis et al., 2012; Oliveira et al., 2015, Dias et al., 2016a; Dias et al., 2016c)
Caffeine	Coffee, tea, chocolate	• Alters Sertoli cells metabolism and oxidative profile	(Dias et al., 2015)

has been included in many fortified foods and supplements to maintain a sufficient daily supply of this vitamin. However, it is known that many men during the reproductive years do not reach the recommended daily dose of vitamin B9. The high intake of folates by healthy non-smoking men has been linked with lower occurrence of aneuploidy in spermatozoa (Young et al., 2008). Moreover, a study performed with subfertile men demonstrated that the consumption of folic acid together with zinc sulfate, led to a 74% improvement in total sperm count (Wong et al., 2002), thus supporting the vital role of vitamin B9 in male fertility potential.

Vitamin C, mostly known as L-ascorbic acid, can be consumed through fruits (e.g. oranges, papaya, strawberries, pineapple) and vegetables (e.g. peppers, broccoli, cauliflower). This vitamin is water-soluble and is part of the antioxidant machinery of seminal plasma, in which it is present at a 10-fold higher concentration than in blood plasma. Sertoli cells seem to be responsible for the availability of vitamin C levels for developing germ cells since they express functionally active vitamin C transporters. Lower levels of vitamin C in the seminal plasma of infertile men (relative to fertile ones) were associated with an increased spermatozoa abnormal morphology (Colagar and Marzony, 2009). Oligospermic men consuming vitamin C showed an overall improvement on sperm quality, including increased sperm counts, motility and normal morphology (Akmal et al., 2006).

Vitamin D is a group of vitamins that human body can generate. In humans, the most important compounds of this group are vitamin D₃ (cholecalciferol) and vitamin D₂ (ergocalciferol). Vitamin D₃ is mainly produced by the epidermis after exposure to sunlight, thus being particularly important for skin health. It is also vital for calcium absorption and hence for bone health. However, it can also be obtained through diet, namely from egg yolks, dairy products and fish (e.g. salmon and sardines). In humans, vitamin D₃ receptor (VDR) is expressed by germ cells and immature Sertoli cells, evidencing the role of this vitamin in

those cells physiology. In fact, the serum levels of vitamin D have been positively correlated with human sperm motility by influencing the intracellular levels of calcium (Jensen et al., 2011). Calcium has a vital role not only in sperm maturation during epididymal transit, but also for acrosome reaction and fertilization.

Vitamin E can be obtained essentially through nuts, seeds and green leafy vegetables, and is one of the primary antioxidant compounds of spermatozoa. The most biologically active form of vitamin E, is α -tocopherol. Vitamin E is a fat-soluble antioxidant and for that reason it can be incorporated into cells membranes, protecting them from lipid peroxidation. It can scavenge lipid peroxyl radicals by generating other radicals, which can be further reduced by other electron donors (usually vitamin C) to return to a stable state, thus blocking the cascade of events that lead to lipids damage. For instance, infertile patients taking a combination of vitamin E and selenium demonstrated an improvement in sperm motility and reduced levels of lipid peroxidation in spermatozoa and seminal plasma (Keskes-Ammar et al., 2003). Additionally, lower levels of α -tocopherol were found in men with oligozoospermia and asthenozoospermia relative to men with normal sperm parameters (Al-Azemi et al., 2009).

Vitamin K is present in many vegetables such as broccoli, cabbage and brussels sprouts and it can be found in two different forms, vitamin K1 (phylloquinone) or vitamin K2 (menaquinone). Only a few studies have evaluated the role of vitamin K in male reproduction. For instance, it has been described that a vitamin K2-dependent protein called osteocalcin, which is secreted by osteoblasts, could promote testosterone production by murine Leydig cells through the binding to a specific receptor - GPRC6A. Although there is a controversy concerning the role of this protein in human testosterone levels and sperm count, one study demonstrated the lack of one of the transmembrane domains of GPRC6A in infertile men, which could prevent the receptor from localizing to the cell membrane (Oury et al., 2013).

Trace Elements

Several trace elements make part of the composition of seminal plasma, including calcium, magnesium, selenium, sodium, potassium and zinc, which are important for sperm physiology. All these elements can be obtained through diet, so variations in the nutritional status of a man can influence the levels of those components in the seminal plasma. These minerals are important for the maintenance of seminal plasma pH and antioxidant potential, thus being important for male fertility. For instance, selenium has a preponderant role in normal testicular development and spermatogenesis. Nuts, fish and beef are some of the selenium-rich food products. Selenium is a constituent of selenoproteins, which are present within spermatozoa midpiece. One major class of functional selenoproteins includes glutathione peroxidase enzymes that are crucial for spermatozoa protection against ROS attack. Lower serum levels of selenium have been described in men with oligospermia and azoospermia compared to fertile ones. Both selenium deficiency or excessive supplementation may lead to decreased sperm motility and increased abnormal morphology (Ahsan et al., 2014).

Zinc is very important for spermatogenesis since it acts as a cofactor of metalloenzymes involved in DNA transcription, expression of steroid hormone receptors, and protein synthesis. Among the zinc-rich foods are seafood, beef/lamb meat and wheat. Fertile men showed higher levels of zinc in the seminal plasma than infertile ones and these levels were positively correlated with sperm counts and normal morphology (Colagar et al., 2009). Moreover, the combined ingestion of zinc with vitamin C and E by older men (>44 years) was associated with lower levels of DNA fragmentation (Schmid et al., 2012).

Other Food Components

Carnitines are lipid-soluble compounds that can be synthesized in the body (25%) from the essential amino acids lysine and methionine, or it can be obtained through diet (75%). They are abundantly present in meat and milk. There are two major forms of carnitines, L-carnitine and acetyl-L-carnitine, which are found in the seminal plasma. The levels of seminal L-carnitine were reported to be lower in infertile individuals, especially when azoospermic, relative to fertile ones (Ahmed et al., 2011), thus evidencing its role in male fertility.

Coenzyme Q10 is a polar ubiquinone involved in the cellular energy metabolism that can also have an antioxidant protective role in cell membranes and lipoproteins. The human body can synthesize coenzyme Q10 through the cholesterol metabolic pathway, but it can also be obtained through diet by consuming salmon, tuna, beef, nuts and seeds. Coenzyme Q10 has a specific role in oxidative phosphorylation by mitochondria, thus being located in sperm midpiece and having a role in ROS control. Significant improvement in sperm density and motility was demonstrated by coenzyme Q10 ingestion (Safarinejad, 2009).

PUFAs are abundant constituents of sperm membranes, being essential to their integrity, fluidity and resistance. There are two main types of PUFAs, omega-3 and omega-6, which are considered essential fatty acids and are mostly obtained through the diet (e.g. fish and nuts). Alterations in dietary PUFAs have been linked with semen quality. In fact, the higher intake of omega-3 and omega-6 fatty acids may improve the antioxidant potential of seminal plasma, thus improving sperm count, motility and normal morphology (Safarinejad et al., 2010).

Catechins are a type of phenolic compounds very abundant in tea, cocoa and berries to which are ascribed a potent antioxidant activity, especially to epigallocatechin-3-gallate (EGCG). This catechin showed the ability to modulate Sertoli cells proliferation and function, having toxic effects at high doses (Dias et al., 2017). EGCG was shown to increase human sperm motility and viability, but at higher doses the opposite effects were observed (De Amicis et al., 2012). Interestingly, the effect of this catechin in sperm quality

seem to be better when acting synergistically with other tea components, including caffeine and L-theanine (Dias et al., 2016a). Caffeine itself has also been reported as a modulator of human Sertoli cells action, thus affecting spermatogenesis and male fertility (Dias et al., 2015). Additionally, the ingestion of white tea by prediabetic rats improved antioxidant defenses (Oliveira et al., 2015) and sperm quality (Dias et al., 2016a). These studies evidence the importance of using adequate doses and combinations between several compounds to reach beneficial outcomes.

Future Perspectives

A balanced diet and lifestyle are crucial to avoid the establishment of an oxidative environment within the male reproductive tract, which has been implicated in the high prevalence of subfertility/infertility. However, further investigation is needed to clarify the link between nutrition and male fertilizing ability, as well as the doses of certain nutrients and other important food components that influence male reproductive potential. Nutritional therapies using antioxidant compounds are frequently used and may be a good approach to restore the capacity of the inner antioxidant system to control the detrimental effects of oxidative stress and enhance natural conception rates. A wide range of antioxidants can be daily consumed through the diet, influencing the overall nutritional status of an individual. This status should be part of the couple evaluation when they seek for medical help to conceive, since it could improve the outcomes of assisted reproductive technologies (ART). Alterations in nutrition and lifestyle are the primary medical recommendations to any treatment since they are easily manipulated factors. However, according to the high prevalence of diet-related diseases, most people are not complying. So, global measures should be taken to make people follow a healthy lifestyle and this should be made at early age to avoid late complications. Further studies and controlled clinical trials are needed to elucidate the possible use of nutritional therapies in the improvement of an individual's reproductive health state, especially in the presence of oxidative stress-related pathological conditions.

The Pineal Gland

The historical identification of the pineal gland has traces in the III and IV centuries BC, when Galen of Pergamon (AD 130–200) appeared to have described the location for this gland in the brain. Later, Andreas Vesalius Bruxellensis (1515–64) reported that this was an unpaired organ with extensive vascularization. The name of this gland itself underwent several alterations throughout time, mostly due to the increasing knowledge of its structure and functioning. The first consistent concept for pineal gland functioning, dated from 1965, was supported on the incomplete definition that the pineal organ was a photoneuroendocrine transducer that converted the coded photic information received into a hormonal signal of light and darkness (Fig. 1). Indeed, the pineal body is the only endocrine gland that is under the influence of the external stimuli received by the retina, thus being responsible for the conversion of those signals into neuroendocrine-mediated effects.

The remarkable anatomical features of the pineal gland, which is a spherical organ located in the midline of the brain, highlight a potential central role for this gland in the individual's physiological functions. Interestingly, most sudden death in infants occur during night and were associated with small pineal glands and with low biosynthetic rates, illustrating that a normal functioning and physiology of this gland is absolutely necessary for a good lifespan. In vertebrates, the pineal gland develops from the neural crest cells of the roof of the diencephalon. It is situated within the brain located adjacent to the superior *colliculi* and behind the *stria medullaris*. Based on this, there were several attempts to make a definitive anatomical classification of the pineal gland for which there is no consensus, though the most used and cited was proposed by Vollrath (1981), which takes in consideration the relative location, shape, and size of the gland. Essentially, he has proposed three anatomical subtypes of pineal glands, mostly according to their relationship with the third ventricle of the brain. The type A pineal rests at a proximal position to the posterior section of the diencephalon, while type AB pineal adopts a proximal intermediate position, and the ABC type is an elongated pineal spanning from the diencephalon till near the cerebellum and adopts a proximal–intermediate–distal position. Still, there is a great variation in the anatomic morphology of the pineal gland across and between species that reflects the adaptive needs for each and the adaptation to environmental factors. In addition, the pineal gland can have a wide range of weights and pineal glands weighing around 1 g were even reported in individuals with genetic disorders associated with insulin resistance. Nevertheless, in human adults without any known disordered clinical condition, the average pineal dimensions are the same as a grain of rice; with no variations according to age or gender. The pineal gland has sympathetic enervation, which consists of noradrenergic fibers, which have a central role for the regulation of the pineal gland functioning. It has also excellent blood irrigation and is usually presented as

Fig. 1 Overview of the mechanism by which light availability modulates melatonin secretion by the pineal gland. This mechanism involves the neural pathway originating in the retina and passing through the suprachiasmatic nucleus, reaching pinealocytes in the pineal gland via adrenergic nerves and adrenergic receptors, and subsequently to the periphery.

the second organ with the highest rate of blood flow per tissue mass, only surpassed by the liver. Thus, there are numerous capillaries within the pineal parenchyma, which allow a greater metabolic activity. Indeed, during the night, when the pineal gland activity is more intense due to increased indole metabolism, the blood supply also increases.

Histologically, the pineal gland presents a parenchyma composed of two types of cells: the pinealocytes and the neuroglia. The former are organized into strings and rest on the basal membrane where they relate with the interstitial space. In fact, the most abundant cells in the pineal body are pinealocytes that produce the pineal hormones, from which melatonin arises as the most relevant for several physiological processes, being that the pineal gland also secretes indoles and polypeptides. In addition, other astrocyte-like interstitial cells were also identified in the pineal gland. Photoreceptors have been found in pineal glands, but mammalian pinealocytes are not capable of directly produce hormones in response to light treatment.

The human pineal is classified as type A. It is positioned within 1–2 mm of the brain midline, which makes it an ideal reference point for the midsagittal plane. The development of the pineal gland starts during the second month of gestation, as an invagination of the ependymal lining of the diencephalic aspect of the third ventricle, between the *habenula* and the posterior commissure, to which it retains connections composed of a rostral and a caudal lamina. The human pineal gland is usually described as consisting of a central core composed of lobules and a cortex with a more diffuse distribution of neurons, being the pinealocyte *sensu stricto* the main cell type. Human pinealocytes are histologically described as having a prominent nucleus and a granular appearance with a cytoplasm and capillaries with characteristic configuration of endocrine glands. Surrounding the pinealocytes, there is neuroglia composed of fibrous astrocytes and microglia. The pineal gland receives blood supply from the branches of the posterior choroidal arteries. In addition, veins and arteries are present in the pineal tissue and there is an extensive internal capillary system, which, together with the fact that it lacks an endothelial blood–brain barrier, makes it very reactive to peripheral drugs. Innervation is also a key feature of the human pineal gland and results from the presence of peripheral sympathetic and parasympathetic fibers, together with fibers originating in the central nervous system (CNS). However, although it is closely located to the midbrain, the pineal gland scarcely receives afferent innervation from the brain itself.

Melatonin

Melatonin (or *N*-acetyl-5-methoxytryptamine) was firstly isolated in 1958 as a pineal gland product and is an evolutionarily conserved molecule, which is often referred as a master regulator of the biological (or circadian) clock. It is a small and very lipophilic indoleamine, with a molecular weight of 232 Da. This hormone is not stored at significant levels in the pinealocytes, but is rapidly released into the bloodstream. Apart from the role of pineal gland in melatonin production, it is also produced in small quantities by other extrapineal organs including the retina, skin, bone marrow cells and ovaries, among others. Nevertheless, in humans, pinealectomy virtually removes all plasma melatonin availability. Melatonin is mostly secreted during the night in humans, as it occurs in most other diurnal species, and the maximum levels detected in the plasma in adults average 60–70 pg/mL, while in saliva are usually one-third lower. Nevertheless, in physiological conditions, melatonin is present in both fluids in concentrations that are usually below 5 pg/mL. In human adults, the peak of melatonin concentration usually occurs between 02.00 and 04.00 h, while the onset of secretion occurs around 21–22.00 h and the offset at 07.00–09.00 h. Moreover, plasma melatonin concentrations reflect the synthesizing activity of the pineal gland, while its concentration in retina and other organs may reflect a local action.

Melatonin Biosynthesis

The precursor for melatonin synthesis is tryptophan, an essential aminoacid uptaken, which is hydroxylated to 5-hydroxytryptophan and then converted into serotonin (Fig. 2). Several food products, like banana, soya, milk, meat, fish or egg, are rich in tryptophan. The rate of melatonin production depends mostly on the activity of the key enzyme aralkylamine *N*-acetyltransferase (AANAT), and to a lesser extent on that of the enzyme tryptophan hydroxylase (TPH). Compelling evidence suggests that AANAT catalyzes the most fundamental step in this pathway since it seems that the key mechanisms that control melatonin production are related with the regulation of its activity (Klein et al., 1997). Nevertheless, the mechanisms that regulate melatonin biosynthesis and AANAT activity vary between species, and there are several other factors that can control the production of melatonin, including the availability of the different intervenients and nutritional factors.

Tryptophan hydroxylase (TPH) catalyzes the conversion of tryptophan to 5-hydroxytryptophan, using tetrahydrobiopterin (BH4) as a pteridine cofactor. Interestingly, the localization of TPH is restricted to serotonin-synthesizing tissues, which highlights the relevance of this enzyme for the process. This enzyme has two main isoforms: TPH1 and TPH2. The former is localized in pineal gland and gut, while the latter is exclusively found in the brain. The regulation of the expression levels of these isoforms follows the clock-driven circadian rhythm, being that the highest values are detected at night, when melatonin levels are known to rise. Notably, when individuals are exposed to light during the night, the levels and activity of TPH drop.

5-Hydroxytryptophan is then readily and freely converted to serotonin by the action of the enzyme DOPA decarboxylase (Fig. 2), with the intervention of vitamin B6. Serotonin is then metabolized into melatonin in two steps. In the first step, *N*-acetyltransferase (AANAT) acetylates serotonin to form *N*-acetylserotonin. The second step occurs by the action of hydroxyindole-*O*-methyltransferase (HIOMT) that converts *N*-acetylserotonin into melatonin (Fig. 2). As referred, AANAT is usually described as the most relevant regulator of melatonin biosynthesis. In vertebrates, AANAT belongs to a superfamily of GCN5-related *N*-acetyltransferases (GNAT), requiring acetyl coenzyme A (AcCoA) as an acetyl group donor and presenting

Fig. 2 Simplified overview of the biosynthetic pathway of melatonin in the pineal gland. Tryptophan is converted to 5-hydroxytryptophan by the action of tryptophan hydroxylase. This latter is converted to serotonin by DOPA decarboxylase, which is later converted to *N*-acetylserotonin by aralkylamine *N*-acetyltransferase. Melatonin is then originated from *N*-acetylserotonin by the action of hydroxyindole *O*-methyltransferase. The action of these enzymes is assisted by several co-factors (not shown).

a catalytic core and regulatory regions. The catalytic core binds to arylalkylamines and acetyl-CoA to facilitate the transfer of the acetyl group. The regulatory regions contain phosphorylation sites that function as regulatory domains for activation and stabilization of the catalytic core. The phosphorylation of those domains promotes the binding to 14-3-3 proteins, which mediate a reduction of the K_m for arylalkylamine substrates and also protects the enzyme from the proteosomal degradation, illustrating a complex functioning. The activity of AANAT can be regulated at three main levels: (1) transcription; (2) posttranscriptional, such as phosphorylation; and (3) binding to chaperones or by processes related with the regulation of protein degradation velocity through proteosomal degradation (for review Karolczak et al., 2005). Nevertheless, the relevance of those mechanisms is species-dependent. For instance, *de novo* transcription is required in rat since during the light phase the transcripts of *Aanat* gene are not detectable, while the increase of norepinephrine (NE) release during the night is followed by a strong increase of approximately 100-fold in the levels of *Aanat* gene, which promotes a rise in the levels of the protein and its activity. However, that is not the case in other species, such as the sheep or the rhesus monkey in which AANAT mRNA levels do not change much during the 24-h of the day and thus, changes in this protein activity are mainly modulated by the levels of the protein itself (Coon et al., 2002).

In addition to melatonin, there are other 5-hydroxyindoles that may also be synthesized in the pineal gland, such as 5-methoxytryptophan, 5-methoxytryptamine, 5-methoxyindole 3-acetic acid, and 5-methoxytryptophol. Nevertheless, the relevant biologically active methoxyindoles are melatonin, 5-methoxytryptophol, and 5-methoxytryptamine.

Regulation of Melatonin Production

Melatonin production is driven by the internal clock mediated by the suprachiasmatic nucleus (SCN) that is connected with the pineal gland. This multisynaptic pathway ends-up in a circuit that consists of sympathetic nerve fibers. Those fibers release NE exclusively at night, complying with the circadian rhythm. Information concerning the light availability is received in the retina and primarily passes through the retinohypothalamic pathway, until it reaches the SCN, where the internal circadian sensitive clock is located. This synchronizes the circadian clock phases with light–dark cycle. It is a complex process in which the SCN fibers pass through the paraventricular hypothalamic nucleus, medial forebrain bundle, and reticular formation. This sends information to the intermediolateral horn cells of the spinal cord, which contain preganglionic sympathetic neurons. The latter terminate on the pinealocytes that are responsible for the release of NE. NE acts as the master neurotransmitter that regulates AANAT action and the synthesis of melatonin in mammals. It stimulates the pinealocytes and initiates a sequence of reactions after activation of two subtypes of receptors, α_1 - and β_1 -adrenergic receptors.

The activation of the α_1 -adrenergic receptors results in a significant increase in the intracellular concentration of calcium ($[Ca^{2+}]_i$) (Schomerus et al., 1995; Sugden et al., 1987). It is known that $[Ca^{2+}]_i$ modulates melatonin biosynthesis in a manner that may be species-specific, though the exact mechanisms remain unknown. Nevertheless, it is known that increased $[Ca^{2+}]_i$ triggers L-glutamate exocytosis from pineal microvesicles, which inhibits NE-mediated melatonin synthesis through paracrine and/or autocrine mechanisms (Yamada et al., 1998a,b). From here, the downstream mechanisms that control AANAT expression

and activity appear to be species-specific. These NE-dependent mechanisms are on the basis of the control of melatonin biosynthesis, which usually is suspended before the end of the night due to several processes, such as attenuation of NE release from the sympathetic nerve fibers as the night progresses, or CREB dephosphorylation.

The activation of the β 1-adrenergic receptors increases the intracellular concentration of cAMP, which is followed by activation of the cAMP-dependent protein kinase A (PKA). This mechanism is common to all mammalian species and results in stimulation of AANAT and melatonin production. The cAMP/PKA pathway controls transcriptional mechanisms that regulate the synthesis of melatonin through the transcription factor cyclic AMP response element (CRE)-binding protein (CREB), which is constitutively expressed in the pineal gland (Klein et al., 1997; Korf et al., 1998). Phosphorylation of CREB enhances the transcription of genes bearing a CRE in their promoter region. The transcription of those genes ends up in the upsurge of AANAT protein levels and activity, which results in increased production of melatonin. Phosphorylated CREB results not only from stimulation of β 1-adrenergic receptors, but also from other cAMP-elevating agents, highlighting the relevance of CREB as a central master regulator of melatonin biosynthesis and production.

When discussing melatonin biosynthesis, one must not overlook the retinal biosynthesis of melatonin and its regulation by dopamine. Dopamine is the major catecholamine of the vertebrate retina and is localized to a subpopulation of amacrine and/or interplexiform cells. Nevertheless, that organization is dependent of the species, though the regulatory functions of dopamine as a biochemical signal for the presence of light is conserved. Indeed, the suppressive effect of light on retinal biosynthesis of melatonin seems to be mediated in part by D_4/D_2 -dopamine receptors that are localized in the photoreceptor cells. Those receptors seem to be involved in the phase-shifting effect controlled by light in the circadian melatonin/AANAT rhythm in some species, such as *xenopus*, but not in the chicken for instance. Interestingly, those D_4/D_2 -dopamine receptors, known regulators of melatonin biosynthesis in the retina, are also known to be indirectly linked in a negative way to the cAMP generating system.

Melatonin Receptors

Melatonin is mainly synthesized and secreted by the pineal gland during the dark phase at night, whose main function is related with the regulation of the circadian rhythm. The major physiological actions of this hormone are primarily mediated by interaction with G protein-coupled transmembrane receptors. Initially, melatonin receptors were divided into two classes, named ML1 and ML2, in accordance with their different affinity and binding kinetics for an agonist radioligand 2-[125 I]iodomelatonin ([125 I] Mel) and differential pharmacological profiles for the synthetic ligands. The ML1 receptors showed a range of affinity considered high (in picomolar concentration) to [125 I]Mel, while ML2 receptors have reportedly a much lower affinity to the radioligand, in a nanomolar range. But further studies revealed that this would not be a definitive classification, exposing new findings concerning the action of melatonin and indeed, up till now seven receptors have been identified. The first melatonin receptor to be discovered was cloned from *Xenopus laevis* and seems to be expressed only in nonmammalian species (Ebisawa et al., 1994).

Subsequently, two different forms of human melatonin receptors were cloned and named as melatonin receptors types 1 and 2 (MT1 and MT2, respectively) (Reppert et al., 1994, 1995). Both receptors have similar binding properties and have subnanomolar affinities for the hormone. Interestingly, a G protein-coupled receptor named GPR50 (or Mel1c), shares 45% amino acid sequence identity with MT1 (or Mel1a) and MT2 (or Mel1b) and, though melatonin does not directly binds to this receptor, it dimerizes with MT1 and MT2 but only inhibits the agonist binding to MT1, preventing the recruitment of signaling partners (Levoe et al., 2006).

Finally, melatonin has been suggested to bind to the orphan nuclear receptor of the retinoic acid receptor family, named as retinoid Z receptor (RZR) and retinoid acid receptor-related orphan receptor (ROR) (Becker-Andre et al., 1994). The RZR/ROR subfamily consists of three subtypes (α , β , γ) and four splice variants of the α -subtype. The mode of action of those receptors regarding melatonin binding and subsequent activity remains unknown.

Melatonin receptors act through a myriad of signaling pathways, including adenylyl cyclase inhibition, phospholipase C stimulation, and other relevant pathways. It is interesting to notice that in birds and lower vertebrates, melatonin receptors are widely distributed throughout the CNS, while in mammals its distribution is by far more restricted (Table 1), being highly weaker than in nonmammal species. Melatonin can induce the activation of different second messenger cascades, depending of the tissue and also of the species, which makes very difficult to understand the specificity of the process since distinct cascades can act on the same receptor subtype. Nevertheless, some specific characteristics are usually attributed to each receptor. For instance, MT1, MT2, and GPR50 receptors are primarily coupled in an inhibitory manner to adenylyl cyclase, cAMP and PKA signaling pathway, respectively. Notably, the hypothalamic neurons in the SCN and the neurons responsible for the secretion of GnRH are the main targets of melatonin in the hypothalamus. Nevertheless, melatonin receptors are disseminated and expressed in the *pars tuberalis* and *pars distalis* of the anterior pituitary (Table 1). The melatonin receptors in the anterior pituitary are time-dependent and it has been described a postnatal decline of those receptors in the *pars distalis* (Johnston et al., 2006). It is also interesting to highlight that melatonin receptors are not only expressed throughout human fetus (Thomas et al., 1998), but the pinealocytes of the fetus are capable to synthesize melatonin as early as the 26th week of gestation which highlights a possible role for this hormone during development.

Bioactivity and Bioavailability of Melatonin

In humans, melatonin secretion varies during the different life periods. It peaks at 3–5 years of age and starts to decrease from puberty onwards, though it is reported that melatonin values are relatively constant until late in life, when a significant decrease

is observed. However, there is a great range of values between individuals, which has captured the attention of the clinicians and researchers to understand if these differences do have an impact in human health. Melatonin intervenes in several important physiological and pathological conditions, including seasonal reproductive cycles in animals, mitochondrial function, cancer, cardiovascular function, cellular metabolism, reproductive system, and immunomodulation, among others. Thus, several clinical applications for melatonin have been highlighted. Due to the presence of the electron-rich aromatic indole ring and/or the absence of phenolic hydrogens in its structure, melatonin has been suggested to be involved in electron exchange, which allows it to neutralize oxygen derived radicals and other cellular oxidants, including peroxy (ROO•), singlet oxygen ($^1\text{O}_2$), hydroperoxide (H_2O_2), superoxide anion radical ($\text{O}_2^{\cdot-}$), hydroxyl radical ($\bullet\text{OH}$), among several others. In addition, the metabolites that result from the reaction between melatonin and free radicals also present interesting antioxidant properties, which makes possible to eliminate several molecules of reactive species with only one molecule of melatonin. Furthermore, melatonin has an indirect antioxidant action by activating endogenous antioxidant enzymes, such as superoxide dismutase or the glutathione peroxidase.

Overall, the biosynthesized melatonin is released into bloodstream and gains access to tissues and organs, interacting with virtually all the major biological processes in the body, through the direct action of melatonin itself or its biological metabolites. Since it is not stored at the pineal gland, though it can be locally produced, the bioavailability of this lipophilic hormone in plasma mostly reflects the activity of the pineal gland. Still, the plasma levels of melatonin are also dependent on its deactivation by the liver. More than 90% of the circulating melatonin is deactivated in this organ. It is firstly hydroxylated at the 6-position by hepatic P450, forming the 6-hydromelatonin, which then conjugates with sulfate and also glucuronic acid at less extent, to be then excreted

in the urine. This catabolism of melatonin is different between species but it is rapid and its half-life in humans after short-term exogenous administration ranges from 10 to 60 min. Also remarkable is the fact that the metabolic breakdown of melatonin produced in retina is distinct of that produced by the pineal gland.

Concluding Remarks

The pineal gland is an essential organ where most of melatonin biosynthesis occurs. It is a complex process that has implications in several physiological functions. Indeed, melatonin is predominantly synthesized in the pineal gland, although it can also be locally synthesized in several tissues. In addition, its production was also reported in edible plants (including fruits, cereals, and aromatic plants), bacteria and even unicellular protists, illustrating the conversed evolutionary relevance of melatonin. The most recognized function of melatonin is to carry information about the photoperiod during each day. That information is then differently used by the cells, tissues and even by the different species. There are several relevant biological functions dependent on melatonin biosynthesis, including seasoning-related processes; reproduction; appetite, body weight and most strikingly, in sleep. In addition, emerging evidence has shown that puberty is also under the influence of melatonin biosynthesis. Notably, the discovery that melatonin has a direct free radical scavenger and indirect antioxidant activity, attributed novel functions to this pineal hormone that go far beyond the classic regulation of seasonal reproductive events, photoperiod-dependent processes and breeding animals. In addition, this pineal hormone is a very safe molecule without known toxicity, even when administered in high doses, such as up to 200 mg/kg daily. Thus, there is a wide range of studies aiming to fill the gap of knowledge on the pharmacological potential of this hormone, particularly the best time and route for administration; the lowest effective dose to achieve the desired effects; the specific duration of treatment for each targeted disorder; frequency of administration; type of formulation; controlled released strategies, among several other crucial mechanisms that remain a matter of intense debate and can only arise after melatonin biosynthesis and action is completely known.

The Pineal Gland and Melatonin

The major regulatory function of the pineal gland is to control several biological rhythms under the influence of the light/dark cycle of the surrounding environment. Pineal gland controls the vertebrate circadian biology in a very strict way. This is mainly achieved by the fluctuation of circulating melatonin levels, as consequence of the regulation of melatonin release into the blood by the dark–light cycle. Levels of *N*-acetylserotonin (NAS) and melatonin secreted by pineal gland are low during the day but increase during the night, and the levels of serotonin (5-HT) are up to 10 times higher during the day than at night. During darkness, the pineal gland is responsible for the increase of the circulating melatonin. Since the relative duration of day and night changes along with the seasons, the light cycle also changes and thus, melatonin concentration in circulation follows those alterations. It is interesting to note that whether the individuals are active during the day (diurnal species), during night (nocturnal species) or at crepuscular period, the levels of melatonin are higher during the night and follow a dark–light cycle. Up until now, only the retina of some salmonoid fish was found to break that rule, with melatonin levels being the same or even higher during the day light, when compared with the dark period. In fact, in lower vertebrates, the role of pineal gland goes far beyond that and functions as a third eye, with pinealocytes themselves containing biologically well-defined photoreceptors that in the presence of light respond just like the retina.

Highly specialized photoreceptors mediate the pineal gland regulatory mechanisms responsive for the precisely timed reproductive events. Those photoreceptors are specialized retinal ganglion cells that contain melanopsin, a unique photopigment. Those cells receive the information concerning the period of the day (light versus dark) via the retinohypothalamic tract to the suprachiasmatic nucleus (SCN) in the anterior hypothalamus. The SCN is then responsible for the transmission of information via central and peripheral sympathetic neurons to the pineal gland. Norepinephrine (NE) is released to the pinealocytes by the neurons and thus, the latter are responsible for the regulation of melatonin production during the night. The regulatory processes and the molecular mechanisms by which pineal gland produces melatonin and modulates the neuroendocrine axis and intervenes in the secretion of gonadotropins and prolactin are under intense research, particularly the effects mediated by the cellular receptors.

In addition to all these regulatory functions, it should also be highlighted that melatonin peak is closely related with central body temperature and some particular characteristics including the maximum fatigue, lowest alert and performance. For example, though the observations are not that consistent, several authors still associate the ovulatory rise in temperature during the menstrual cycle with a consistent decline in melatonin, while the concentration of melatonin during the luteal phase is suggested to be higher than during the follicular phase. This is still a matter of debate and remains one of the main unveiled mechanisms for melatonin function.

Melatonin and Reproductive Function

The pineal gland functioning, primarily through melatonin biosynthesis and action, has been extensively characterized and associated with several aspects of mammalian physiology, as for instance the reproductive function (Fig. 1). Some of those are quite remarkable, with melatonin being proposed to have a role in the selection of the sexual partner in zebra finches (*Taeniopygia guttata*) by at least two possible mechanisms: one related with its antioxidant activity that affects the color and pigmentation; the other related with melatonin receptors localization in the neurons of the sensorimotor areas which could intervene with the song pattern, known to be essential for mating in male zebra finches (for review (Reiter et al., 2009)).

There is also compelling evidence for a role of melatonin in human reproduction, particularly due to its correlation with gonadotrophins and steroids. Those findings suggest that melatonin may play a role in sexual maturation, control of puberty onset, folliculogenesis, spermatogenesis, oocyte maturation, ovulation, sperm activation, sperm-oocyte fusion, pregnancy and menopause (Rocha et al., 2015). Melatonin is expected to indirectly alter gonadal function through gonadotropin-releasing hormone (GnRH) and gonadotropin secretion, but direct effects may also occur since melatonin can be synthesized in the gonads. The direct action of melatonin is expected to influence steroids production and action as well as major cellular signals in those tissues. In mammals it has been described that melatonin influences the reproductive function by activating melatonin receptors sites that are distributed throughout the HPG axis, particularly in the hypothalamic neurons, which are responsible for the release of GnRH. The activation of those receptors decreases the production of cyclic AMP, as well as the activity of the protein kinase A and induces a decrease on GnRH-induced gonadotropin secretion. This is mainly caused by suppression of GnRH-stimulated calcium signaling due to activation of melatonin-mediated signaling (Ishii et al., 2009). The processes related with calcium mobilization from intracellular stores and the influx through voltage-dependent channels are inhibited by melatonin, mostly likely due

Fig. 1 Overview of the main melatonin functions in male and female reproductive gonads. In males, melatonin is capable of acting directly in the hypothalamic–pituitary axis, modulating the production and release of gonadotropins, which regulate testicular function (particularly spermatogenesis and testosterone synthesis). Melatonin is also able to directly influence sperm quality through its anti-apoptotic and radical scavenger properties. The antioxidant properties of melatonin allow the lessening of testicular damage in pathogenic conditions characterized by an overproduction of reactive oxygen species (such as in episodes of ischemia/reperfusion, in diabetes mellitus and obesity, among others). The ability to scavenge many types of radicals extends to the female reproductive tract, also by enhancing the antioxidant defenses, by regulating antioxidant enzymes like catalase, superoxide dismutase and glutathione peroxidase. In the female gonads, melatonin has the ability to enhance the follicular steroidogenesis, and to be directly involved in oocytes physiology, particularly its growth, maturity and in other factors that control oocyte quality. Up arrow, increase; down arrow, decrease; ROS, reactive oxygen species.

to AMP/protein kinase C-mediated signaling (Zemkova and Vanecek, 1997). Those events seem to decline with age, promoting some disorders mostly due to a reduction in the expression of functional melatonin receptors.

More recently, it has also been suggested that melatonin can act directly on the cells that produce the gonadotropin-inhibitory hormone (GnIH), a multifunctional neuropeptide whose expression and synthesis increase on short days that abundantly express melatonin receptors (Bentley et al., 2009). Moreover, melatonin was reported not only to increase the number of GnRH-secreting cells, which has a relevant impact in the neuroendocrine activity, but it does not affect the size or morphology of those cells (Glass and Knotts, 1987). Thus, it has been suggested that the effect of melatonin in the hypothalamus is mediated by suppression of GnRH release, rather than its synthesis. Melatonin is also known to inhibit the expression of several hypothalamic genes, especially kisspeptin, which has been shown to act as modulator of GnRH release in breeders. All these evidence shows that melatonin interferes with GnRH release but it is unclear whether it can directly act on GnRH neurons or whether up- or downstream regulators of GnRH neurons mediate the actions.

Melatonin and Puberty Onset

The first evidence that melatonin could be involved in the control of the reproductive function was reported in 1963, in a study showing that the exogenous administration of melatonin reduced the weight of female rats ovaries (Wurtman et al., 1963). Since then, a growing number of reports have emerged exposing several regulatory functions of pineal gland, particularly through melatonin, in the reproductive function. For instance, melatonin has been suggested to play a pivotal role during puberty onset. In rats, the process of reproductive maturity was shown to be finely controlled by melatonin, as injections of this hormone during different light periods or dark phase of the pubertal development result in delay of reproductive development in both males and females without compromising the full process (Horton et al., 1989). Ovaries and testes maturation is triggered by secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), under pulsatile GnRH secretion. Melatonin was suggested to interact in that cascade by triggering the hypothalamus through molecular mechanisms that remain unknown. It seems that before puberty, the concentrations of melatonin are too high for hypothalamic activation to occur. However, by the onset of puberty, there is a decline in the serum levels of melatonin, triggering GnRH, which is pivotal for it to start. This reactivation of the hypothalamic–pituitary axis by the amplitude and frequency of GnRH pulses follows the pulsatile secretion of FSH and LH that triggers puberty. The role of melatonin in the onset of puberty is also highlighted by studies showing that children with delayed puberty

have high levels of nocturnal melatonin, whereas children with precocious puberty present low nocturnal melatonin levels (Waldhauser et al., 1991). In addition, there is clear evidence that melatonin is involved in the control of the pulsatile secretion of LH (Brzezinski et al., 1987) and there is a negative correlation between nocturnal melatonin and LH levels (Waldhauser et al., 1984). Interestingly, it was reported that melatonin serum levels in humans increase during the dark periods in winter and that this is related with reduced activity of the anterior pituitary–ovarian axis (Kauppila et al., 1987). Contrastingly, plasma levels of LH are higher in summer than in winter when the dark period is longer (Kivela et al., 1988). It was also shown that melatonin passes to the fetus through the placenta and by the umbilical cord illustrating that even during pregnancy, this hormone has a preponderant role.

Melatonin and Female Reproductive Function

Melatonin is also well known for its direct effects in the ovaries, which has implications in female reproduction (Fig. 1). Ovarian granulosa and theca cells, which are known to promote steroid hormone production and are present in mature follicles and in the corpus luteum (CL), possess melatonin receptors. In addition, melatonin seems to be directly involved in oocytes physiology, particularly its growth, maturity and in other factors that control oocyte quality. Interestingly, measurements of melatonin levels showed that these are higher in human ovarian follicular fluid (FF) than in plasma and depend on follicular growth. That is suggested to occur due to a high transport of melatonin from the bloodstream, but also due to local synthesis mostly by granulosa cells (Tamura et al., 2009). Among the several functions of melatonin in the ovary, it appears that this hormone is involved in follicular steroidogenesis via modulation of cAMP and also the expression of the steroidogenic acute regulatory protein (StAR). Melatonin influences the production of sex steroids at different stages of follicle maturation by inhibiting the expression of the steroidogenic genes *CYP11A* and *CYP17*. In humans it was shown that melatonin can change the follicular response to LH by elevating the mRNA expression of LH receptors in granulosa cells. It was also shown that this hormone promotes follicular development since it may increase the production of insulin-like growth factor I, which is known to stimulate the mitogenic growth of granulosa cells.

Also interesting is the fact that human births occur more frequently at night when the levels of melatonin are higher, which illustrates a possible role for melatonin on that process. That is also supported by the fact that myometrial cell membranes possess melatonin receptors. Indeed, MTNR1B levels were found to be upregulated in myometrium cells of women during labor and melatonin synergizes with oxytocin to promote and coordinate muscle contraction (Sharkey et al., 2009). Treatment of several diseases that occur during pregnancy may also benefit from melatonin and pineal gland function. For instance, preeclampsia, a condition that affects a high number of pregnant women, whose major signs include elevated systolic and diastolic blood pressures and proteinuria that can progress into both mother and fetal complications, was ameliorated by melatonin treatment. This is a condition that might be associated with increased oxidative stress and low antioxidant defenses thus, melatonin has great therapeutic potential.

Melatonin seems to have a role also during menopause. Women face a series of alterations during and after menopause that have an impact in their health, including hot flushes, mood disturbances, vulvovaginal atrophy, muscle weakness, bone mass loss and sexual dysfunction, among other health problems. In addition, there is a higher risk for the development of cardiovascular diseases, breast cancer and even Alzheimer's disease, among other conditions. The treatment of women in post-menopause with melatonin can elicit positive effects in most of those health conditions. For instance, it can revert some hormonal disturbances and menopause-related depression. In addition, it also has the ability to restore menstrual cycles and fertility in peri- or premenopausal women. Nevertheless, the mechanisms that mediate those effects are still under intense research and remain unknown.

Melatonin and Male Reproductive Function

Melatonin is also essential for male reproduction and testicular function. It has direct and indirect effects on testicular cells and sperm quality (Fig. 1). In males, it is known that melatonin alters the secretion of two key neurohormones, GnRH and LH; it also regulates the synthesis of testosterone and testicular maturation. The regulation of testosterone secretion by melatonin is still unclear, since it is a very complex process that depends not only on the indirect pathways involving the hypothalamic–pituitary–gonadal axis, but also on direct effects on Leydig cells. Indeed, melatonin receptors have been identified in several testicular cells (for review (Rocha et al., 2015)). By acting in Leydig cells, melatonin is reported to regulate testicular growth. In addition, melatonin receptors were identified in Sertoli cells, and in vitro exposure to melatonin modulated the nutritional support of spermatogenesis by these cells (Rocha et al., 2014) by enhancing glucose consumption though producing less lactate. Interestingly, treatment of Sertoli cells with melatonin plus insulin increased the efficiency of lactate production. This metabolite has a crucial role for spermatogenesis since it is an anti-apoptotic factor and a main energy source for developing germ cells.

Melatonin also interferes with the morphology of the male reproductive system, since its administration can cause atrophy and reduction of the seminiferous tubules diameter, which can arrest spermatogenesis. In addition, it can change the morphology of testicular cells. For instance, exposure to melatonin led to alterations in Leydig cells morphology, particularly by decreasing the size and reducing the cytoplasm. Melatonin can also act locally as an inhibitor of androgen production by promoting a downregulation of the expression of steroidogenic acute regulatory protein and key enzymes related with that process (Rossi et al., 2012). These studies illustrate that the regulatory function of pineal gland on male reproductive health, through melatonin, is finely tuned and depends of several aspects, including duration, intensity, and complexity of exposure, among others.

The effects of melatonin on sperm quality has also been reported (Luboshitzky et al., 2002) and widely inferred since its receptors are widely distributed in epididymis, prostate cells and even in spermatozoa. Indeed, several parameters associated with sperm

quality, including concentration, count and motility, are significantly lower during the summer when the days are longer (Levine et al., 1990), suggesting that melatonin has a regulatory role of sperm production and quality. In addition, melatonin was detected in human seminal fluid.

Melatonin Antioxidant Properties and Reproductive Function

The antioxidant properties of melatonin also play a pivotal role in melatonin action on reproductive function. This hormone is known to neutralize the highly reactive hydroxyl radicals resulting from oxygen- and nitrogen-based reactants in an antioxidant cascade, in which melatonin interacts with oxidants species generating further molecular species with important antioxidant properties (Fig. 2). In addition, melatonin boosts the expression and activity of antioxidant enzymes, such as superoxide dismutase (SOD) or the glutathione peroxidase (GPX), while can also inhibit the activity of pro-oxidative enzymes such as the nitric oxide synthase (NOS). Thus, the regulatory function of melatonin in several reproductive tissues, including the FF and seminal fluid, is strictly associated with its antioxidant activity, including a decrease in DNA damage resulting from lipid oxidation (Acuna-Castroviejo et al., 2007), which is correlated with ovum and sperm quality.

Melatonin stimulates maturation-inducing hormone (MIH (17α , 20β -dihydroxy-4-pregnen-3-one)), which heightens oocyte maturation (Reiter et al., 2014; Tamura et al., 2009). During ovulation, reactive oxygen species (ROS) and nitrogen species (RNS) are generated at high quantities, which can promote a high level of oxidative damage. The oxidative balance is very important at this step since ROS may act as second messengers controlling the expression of relevant genes for a regular maturation of the oocytes. On the other hand, a significant increase in ROS may result in damages in oocyte and granulosa cell membrane and structure. Thus, this strict control of oxidative environment is mandatory. In addition, melatonin can have a regulatory function in embryo development. For instance, inseminated mice embryos cultured in a medium supplemented with melatonin have higher rates of fertilization and blastocyst (Ishizuka et al., 2000). This beneficial effect was attributed to the high antioxidant activity of melatonin. In humans, these properties of melatonin are difficult to confirm. However, a recent study showed that infertile women seeking for assisted reproductive technology, in vitro fertilization and embryo transfer taking 3 mg of melatonin a day from day 5 of the previous menstrual cycle to the day of oocyte retrieval had a significant higher percentage of good embryos in the 2nd day after insemination when compared with the control cycle where there was no melatonin treatment (Tamura et al., 2012). Thus, data provide compelling evidence that melatonin is involved in fertilization and pregnancy due to direct and indirect effects.

Fig. 2 Simplified overview of the antioxidant cascade of melatonin. When melatonin interacts with oxidants species it can generate cyclic 3-hydroxymelatonin and *N*¹-acetyl-*N*²-formyl-5-methoxykynuramine (AFMK). Both these compounds are also radical scavengers leading to the formation of *N*¹-acetyl-5-methoxykynuramine (AMK). This latter molecule is a radical scavenger as well. This cascade of reactions increases the effective concentration and scavenging capacity of melatonin.

Melatonin's antioxidant properties are also very important to prevent testicular damage caused by environmental aggressions or inflammation. Testicular torsion, which is a common and frequent pathology, induces several damages that can be prevented by treatment with melatonin which can decrease germ cell apoptosis, increase cell proliferation and testosterone production (Kanter, 2010). Most of those effects seem to be mediated by the antioxidant effect of melatonin that prevents the boost of free radicals that are formed during testicular torsion. That process is also suggested to mediate several other regulatory functions of melatonin in male reproductive system, particularly in sperm, since the increase of free radicals is directly correlated with poor semen quality and function. Spermatozoa are very susceptible to oxidative stress due to the presence of a large quantity of polyunsaturated fatty acids in their membranes along with a low quantity of antioxidant scavenging enzymes. There are several studies showing a positive effect of melatonin supplementation in sperm quality but the mechanisms by which it acts remain a matter of debate. Further studies are still needed to elucidate the molecular regulatory function of melatonin in sperm production and function. Moreover, melatonin has also been reported to prevent testicular damages and dysfunction promoted by toxic agents, such as bisphenol A, cadmium, diazinon, among others. The treatment of mice with melatonin after exposure to a chemotherapeutic agent, cyclophosphamide, reduced testicular lipid peroxidation and other oxidative damages illustrating the potential of this hormone to protect the male reproductive system during chemotherapy.

The aging-associated regulatory functions of the pineal gland are also under constant debate and might contribute to the reproductive decline that is frequently linked with aging. It has been shown that endogenous levels of melatonin consistently decrease with age and thus, the regulatory function of pineal gland becomes very relevant as the lack of the antioxidant properties of melatonin may result in oxidative damage in cells. Thus, it is still under debate the contribution of decreased pineal gland functioning during aging and its reproductive outcomes. Obviously, all circadian rhythm disorders such as jet lag, sleep-related problems and syndromes, including those in the elderly, are under the regulatory function of the pineal gland. Thus, taking in consideration the enormous range of pathologies and the high prevalence of those disorders, the biological regulatory function of pineal gland have emerged as a major clinical field of research.

Concluding Remarks

The regulatory functions of the pineal gland occur through several mechanisms, mostly orchestrated by melatonin, which exerts an action at multiple levels. However, melatonin is not just a pineal hormone since it is also peripherally produced by other organs. It regulates several relevant biological processes and not only reproduction, including in humans. In addition, some important regulatory functions of pineal gland are manipulated by melatonin administration to simulate a different photoperiod. That has important commercial relevance since it can, for instance, allow the control of reproduction in ruminants or the winter coat in most species including cashmere of goats and arctic foxes.

Melatonin is a molecule with multitasking properties and currently, clinical evidence supports a key role for this hormone in reproduction and reproductive processes both, in males and females. In addition, it appears as pivotal for puberty onset but it is difficult to study the specific signals coordinated by pineal gland as during this period there is a complex interplay among neuropeptides, neurotransmitters, steroids and other molecules that interact with the hypothalamic–pituitary–ovarian and the hypothalamic–pituitary–testis axes. Thus, contrarily to hormones synthesized in other glands, melatonin's optimal concentrations for each effect remains obscure and much research is still needed. In addition, most studies are performed in rodents making it very difficult to extrapolate to humans. Currently, melatonin-based therapies are still under debate and studies are needed to consubstantiate the health benefits of this hormone for each particular condition. The pineal gland emerged as an important regulatory organ of several pivotal functions, including reproduction since melatonin has a very low toxicity and can readily cross biological barriers such as the blood testis barrier.

Introduction

The Need for Contraception

Unintended pregnancies are unwanted, mistimed, or both unwanted and mistimed. Almost half of all pregnancies that occur in industrialized nations are unintended. Unintended pregnancies increase the risk for lower birth weights, poorer health outcomes, retarded development, and compromised education in the offspring, as well as postpartum depression and ongoing mental health problems in the mother. These adverse health and social consequences impact the entire family, and result in substantial societal costs that have been estimated to exceed \$15 billion in a single year in the United States alone. Broadening contraceptive choice by allowing both men and women to fully share family planning responsibilities would promote important, but largely unmet individual, couple, and societal needs; reduce the number of elective terminations; and decrease overpopulation.

In the United States, 30% of couples rely solely on a male-directed method (male sterilization, condom, withdrawal). However, the proportion of all couples that are using male-directed methods varies greatly from 0% to 50% throughout the world. Given this variability, the median (rather than the average) proportion of couples using male-directed methods across over 60 nations surveyed is approximately 10% ([United Nations, 2015](#)). After excluding couples that are not using any male or female-directed contraceptive method, about 20%, and up to 80% in some countries, rely on a male-directed method. These data confirm that many couples already depend upon male-directed methods despite such methods being far from ideal. Usage would presumably be even greater if male-directed methods could be developed that were more effective, convenient, reversible, and safe.

Features of an Ideal Contraceptive

An ideal male-directed contraceptive is safe, rapidly and consistently effective (i.e., usable by all men) and rapidly and consistently reversible (i.e., reversible in all men). In contrast, the two currently available male-directed methods are not widely acceptable because vasectomies are not easily reversible and condoms are not very effective. During the last few decades, many new female-directed reversible hormonal contraceptive options including pills, patches, injections, implants, and intrauterine devices with various drug and dose combinations have been marketed. In contrast, there has not been a single reversible male-directed contraceptive developed over this same period. Currently, the only reversible male-directed method available is the condom, which was invented 400 years ago and has failure rates as high as 20% in the first year. New and effective options are needed to broaden choice for couples.

Male Hormonal Contraception

Summary

More than 2000 eugonadal men with unimpaired fertility at baseline have been exposed to over 2000 person-years of male hormonal contraception (MHC, consisting of androgens with or without progestins) to assess contraceptive efficacy (i.e., the ability to prevent pregnancies) ([Table 1](#)). These studies show the effectiveness, reversibility and short-term safety of MHC. MHC satisfies many of the requirements for an ideal contraceptive method that is male-directed. The hope is that a range of MHC treatment options will become available to fulfill differing needs and preferences of couples.

Androgen-progestin MHC treatment regimens reduce sperm output and induce a predictable degree of infertility by exploiting the negative feedback suppression of pituitary gonadotropin secretion by sex hormones. The goal of male hormonal contraceptive methods, according to expert consensus opinion, is to achieve and maintain severe oligozoospermia, defined as a sperm concentration in the ejaculate that is below 1 million/mL, in all users. If this can be consistently achieved and maintained, then contraceptive failure (i.e., pregnancy) rates of 0.6 (95% confidence interval CI 0.09–2.7) % per year can be expected ([WHO Task Force on Methods for the Regulation of Male Fertility, 1996](#)). These failure rates are comparable to those achieved with perfect use of female hormonal contraceptive methods. Even higher failure rates of 1.4 (0.4–3.7) % occur with a higher threshold of 3 million/mL. These data indicate that the degree of infertility induced can be predicted from the semen analysis, and is consistent with semen analysis being the most widely used clinical measure of spermatogenesis and male fecundity.

Mechanism of Action

Spermatogenesis is tightly regulated by the hypothalamo-pituitary-gonadal network through stimulatory feedforward and inhibitory feedback signaling ([Liu and Veldhuis, 2014](#)). The decapeptide, gonadotropin-releasing hormone (GnRH), is secreted in a pulsatile and synchronized fashion by approximately 1200 specialized neurons in the arcuate-nucleus of the mediobasal hypothalamus of the human. GnRH is secreted in minute quantities directly into a portal microvasculature system, where anatomical proximity

allows entrainment of pituitary gonadotropes to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Pulsatile LH and pulsatile FSH circulate and act on distant testicular Leydig and Sertoli cells, to stimulate testosterone production and spermatogenesis, respectively. Circulating testosterone inhibits both hypothalamic GnRH, and pituitary LH and FSH secretion. The feedback inhibition of pituitary gonadotropins is through local aromatization to estradiol. Both FSH and high intratesticular levels of testosterone are required for spermatogenesis.

Male hormonal contraception exploits this negative feedback inhibition to impair spermatogenesis, in a manner that is analogous to female hormonal methods that prevent ovulation. The administration of exogenous androgens, with or without the addition of progestins, suppresses GnRH, LH, and FSH, reduces testicular testosterone concentrations and impairs spermatogenesis. In this context, exogenous progestins act to augment inhibition of the secretion of pituitary gonadotropins, so that unequivocally supraphysiological exogenous testosterone administration is no longer required. Other compounds could also be used alone or in combination to suppress pituitary gonadotropins more completely. Some of these, such as GnRH antagonists or non-pulsatile GnRH analogues that downregulate the GnRH receptor, have already been shown to reduce sperm output in humans, whereas other putative compounds that act upstream of the GnRH neuron through the kisspeptin-neurokinin B-dynorphin pathway remain to be directly tested for contraceptive efficacy. In all male hormonal contraceptive methods, testosterone or another androgen must be administered to maintain systemic testosterone exposure, in order to prevent the symptoms and consequences of unwanted hypogonadism.

Suppression of LH and FSH acutely decreases type B spermatogonia and blocks spermatogonial differentiation. A reduction in round and elongated spermatid production, and ultimately spermatozoa concentrations in the ejaculate, will therefore occur, but requires several weeks due to the duration of the spermatogenic cycle. Whereas azoospermia, the complete absence of spermatozoa in the ejaculate, would render fertilization impossible, this has not been consistently achievable with MHC in all users, nor has it proved necessary. Mechanistically, the physiological bases to explain why 5%–15% of men do not ever suppress sperm output to the desired goal of < 1 million/mL, are unknown. It could be that some men have low basal levels of gonadotropin independent spermatogenesis. Alternatively, the administration of exogenous testosterone itself could raise intratesticular testosterone by advection or diffusion sufficiently to maintain a low level of spermatogenesis in some men. In fact, these very low concentrations of intratesticular testosterone are able to maintain spermatogenesis in rodents and non-human primates; and there is no definable dose of testosterone that would both maintain sexual function and suppress gonadotropins without also activating spermatogenesis in rodents. Indirect evidence in humans supports this contention since the use of higher effective testosterone doses as part of MHC results in a greater proportion of men maintaining a low level of spermatogenesis (i.e., less complete suppression of sperm output) (Liu et al., 2008). However, intratesticular testosterone concentrations have not been consistently different between men who respond with lower or higher sperm output while taking MHC (Roth et al., 2016). Nevertheless, using the lowest effective dose of testosterone is advisable to reduce the theoretical risk of breakthrough spermatogenesis, and decrease androgenic side effects such as acne and male pattern balding.

Acceptability of MHC by Couples

Surveys of actual self-reported behaviors show that the male partner is solely responsible for the couple's contraceptive needs in a large proportion, indicating that women can and do trust their partners to share the responsibility to space and time pregnancies. Consistent with this finding, women surveyed concerning their attitudes to a theoretical MHC also indicate that this would be acceptable to them, provided it was a decision shared with their male partner, not with any man in general (Wang et al., 2016). At least a quarter of men, and in some cases many more, would be willing to use male hormonal contraception. These data together suggest that MHC would be widely used by men in cooperation with their female partners, if and when such methods become available. Furthermore, these surveys of a theoretical MHC were conducted in many large cities in Asia, North and South America, Europe and Africa, and indicate that MHC is acceptable by many couples from very diverse backgrounds throughout the world. However, marked geographical variability in theoretical acceptability was apparent, and is consistent with data of actual usage of existing male-directed methods (male sterilization, condom, withdrawal) discussed earlier. Understanding the cultural, religious or other attitudes that underpin this variability may inform strategies to improve usage of male-directed methods in general. Societal changes in attitudes as well as drug development may therefore both be needed to increase usage.

Men participating in MHC studies report that intramuscular injections every 1–3 months, subcutaneous implants every 3 months, or transdermal gels applied every day are acceptable contraceptive methods; however the reports may be biased by selection for, and active participation in, a clinical trial. Reliably understanding the factors that influence acceptability of MHC may therefore require such methods to first become available. Surveys of men contemplating the use of a theoretical MHC product indicate greater acceptability with oral mode of delivery, and higher income and education. However, female-directed methods that require daily dosing are less reliable due to irregular compliance, compared with long-term injectable and implantable contraceptive options. Male-directed methods that also require daily dosing (such as oral or transdermal delivery) are therefore also likely to be less reliable with typical, rather than perfect use. Nevertheless, data from potential users, and actual participants in clinical trials of specific MHC, both indicate that MHC is acceptable to many men and their partners. Multiple MHC treatment options, as exists for female-directed methods, need to be developed to broaden choice.

Effectiveness of MHC

The contraceptive effectiveness of MHC is highly predictable and varies depending on the threshold sperm output achieved, and how consistently suppression to this threshold can be maintained. Mechanistically, this contrasts greatly with hormonal methods in women which either prevent, or do not prevent, ovulation during each menstrual cycle. Men have been exposed to over 3000 person years of androgens with or without progestins, administered to determine the effect on sperm output, or on contraceptive failure rates. Although androgen-progestin drug combinations account for less than one-fifth of the total exposure, many different drug combinations have already been evaluated. This is because the specific delivery, dose and drug combination influences the rate and extent of spermatogenic suppression, which must be individually quantified in order to plan for a large scale contraceptive efficacy study (Liu et al., 2008). To date, only testosterone, or combinations of testosterone with a progestin, have been evaluated to determine contraceptive failure rates (Table 1). However, two novel synthetic androgens, 7- α -methyl-19-nortestosterone and dimethandrolone (7 α , 11 β -methyl-19-nortestosterone), have undergone preliminary testing of formulation and dose in humans, with suppression of sperm output as the surrogate endpoint. Both androgens are considerably more potent than testosterone, dimethandrolone also exhibits progestational activity, but cannot be aromatized, whereas 7- α -methyl-19-nortestosterone lacks progestational activity, is aromatized, but is resistant to 5- α reduction. These biochemical characteristics may allow for the development of a single oral agent with both androgenic and progestational activity (dimethandrolone), or a more favorable risk profile that spares the prostate from overandrogenization by preventing 5- α reduction (7- α -methyl-19-nortestosterone). Other synthetic androgens could also be developed with specific properties designed to increase effectiveness or limit adverse effects.

Weekly supraphysiological testosterone therapy is a highly effective contraceptive (i.e., prevents pregnancies) and profoundly suppresses spermatogenesis through negative feedback inhibition of gonadotropins (WHO Task Force on Methods for the Regulation of Male Fertility, 1990, 1996; Table 1). Longer-acting testosterone formulations administered alone (McLachlan et al., 2000; Gu et al., 2003, 2009) or in combination with either depot medroxyprogesterone acetate (DMPA) (Turner et al., 2003) or norethisterone enanthate (NET-EN) (Behre et al., 2016) are also highly effective (Table 1). Individual large scale studies show contraceptive failure rates of 0.8%–2.3%, with upper 95% confidence limits of 1.8%–5.8% (Table 1). However, some of these studies did not target sperm concentration to <1 million/mL, and hence may not be applicable for future MHC development.

An integrated analysis of individual participant data of all then-available studies report that 50% and 85% of men suppress sperm output to concentrations compatible with reliable contraception (<1 million/mL), by 3 and 6 months, respectively (Liu et al., 2008). However, this analysis included many exploratory MHC regimens where drug dose and frequency had not yet been optimized. More realistic estimates would be obtained by only examining contraceptive efficacy studies, which are usually extensively tested and optimized. These show that 80%–95% of men suppress sperm output to a threshold of 1 million/mL by 3 months (Table 1). The timeframe for this reduction in sperm output compares favorably with the disappearance of sperm after vasectomy.

Progestin co-administration enhances both the rate and extent of sperm output suppression by up to two-fold (Liu et al., 2008). Certain progestins are likely to be more effective in suppressing sperm output than others, due to differences in binding and

activation of progesterone and other steroid receptors. Pharmacokinetic differences are known to explain variation in anovulatory potency and the ability to support pregnancy in women. The hope is that a fully optimized androgen-progestin combination could be utilized by all men within a practical timeframe. To date however, at least 5% of men enrolled in MHC trials never suppress spermatogenesis to levels required for reliable contraception, for mechanistic reasons that are not entirely clear. Another limitation of the method is that sperm rebound, which occurs when sperm suppression below the target threshold is not maintained, is observed in approximately 2% of men. Specifically, 20 (1.7%) of 1193 men who initially suppressed sperm output to below the target of 1 million/mL experienced sperm rebound (Table 1). There have not been systematic attempts to determine the characteristics of this group of men, and the mechanisms underlying sperm rebound are not known. Sperm rebound is analogous to breakthrough ovulation that can sometimes occur in women, particularly when using lower dose hormonal contraceptive methods. In men, it cannot be solely explained by poor compliance since study personnel administered MHC in many of these studies.

It is also possible that MHC may not universally suppress sperm output adequately in all men, even after extensive drug and dose optimization. Being able to predict non-suppression for any given drug and dose combination used for MHC would then be important. Systematic analyses show that Caucasian ethnicity and higher BMI are important predictors of non-suppression, although the effect of BMI is small and may not be clinically relevant (Liu et al., 2008). Slower spermatogenic suppression occurs in Asian men, and also with older age, higher baseline testosterone and higher initial sperm concentration, but the independent effect sizes of these latter parameters are small. The large and differing effects of ethnicity on the rate and extent of spermatogenic suppression observed between Caucasian and Asian men may eventually be explained by pharmacogenetic differences, which may ultimately unveil more specific methods to identify the small number of men who do not suppress sperm output adequately.

Reversibility of MHC

An integrated analysis of individual participant data of all then-available studies demonstrated that it is realistic to expect full recovery of spermatogenesis to levels consistent with normal male fertility for all men ceasing male hormonal contraceptives (Liu et al., 2006). At the time, normal male fertility was defined by a sperm concentration of at least 20 million/mL, although sperm concentrations of only 13–15 million/mL are now known to be sufficient, based on an analysis published in 2010 (Cooper et al., 2010). Recovery of sperm output to concentrations consistent with normal male fertility occurs in more than 50% of all men after 6 months, and over 90% of all men by 12 months. The remaining men, if not all men who should recover, do so within 24 months. Older age, Asian ethnicity, lower baseline LH concentration, higher initial sperm concentration and faster initial suppression of sperm output predicted faster recovery. Amongst treatment-related factors, shorter treatment duration and the use of shorter-acting testosterone formulations were associated with faster recovery. Treatment duration had the largest clinically important effect.

Since the publication of the integrated analysis, three large studies, including two contraceptive efficacy studies (Gu et al., 2009; Behre et al., 2016), have been completed (Gu et al., 2009; Mommers et al., 2008; Behre et al., 2016). The first study was conducted in China (Gu et al., 2009), and reported a median time of 7.6 months for sperm output to recover to 20 million/mL (Gu et al., 2009). This is considerably slower than the median recovery time of 3.4 (95%CI 3.2–3.5) months calculated from all previous studies, particularly since faster recovery would have been anticipated for this Asian population (Liu et al., 2006). However, the slower recovery was likely explained by the longer treatment duration of up to 30 months, compared with 12–18 months utilized in all other studies (Table 2). The timeframe for recovery of sperm output following cessation of MHC in this study was also consistent with the previous analyses: all except 17 men had recovered by 12 months, and by 15 months one man had a sperm concentration of 13 M/mL (and was then not followed up) and the other presumably never recovered due to intercurrent epididymitis (Gu et al., 2009). The second study was conducted in Europe (Mommers et al., 2008), and 354 men were randomized to receive placebo (53 men) or various regimens of testosterone and the progestin, etonogestrel, to assess suppression of sperm output. The use of a placebo was possible because sperm output, not contraceptive efficacy (i.e., pregnancy rates) was being assessed. Men were treated for 42 or 44 weeks, and amongst those who received active therapy, the median time to recover to a sperm concentration of 20 million/mL was 3.5 months, and by 16 months all men completing follow up had recovered. These data are also compatible with the earlier integrated analysis. Remarkably, two or three men treated with placebo had sperm concentrations <20 million/mL at every assessment during the 24 week follow-up, and up to 14 men (28% of all men treated with placebo) did not consistently maintain sperm concentrations above 20 million/mL during the recovery period. These data from men treated with placebo indicates that supposed non-recovery of sperm output documented in a small number of men treated with MCH could represent regression to the mean, the occurrence of an intercurrent partially sterilizing illness, or both.

The final study was sponsored by the World Health Organization and was conducted in Europe, Asia, South America, and Australia (Behre et al., 2016). Men were treated with a testosterone-progestin combination for up to 18 months, 266 men suppressed sperm output to <1 million/mL, and 96 of these men were discontinued because the study was prematurely terminated (see next section on adverse events). Unlike any of the earlier contraceptive efficacy studies, normal male fertility was defined by a sperm concentration of 15 million/mL or a total sperm count of 39 million per ejaculate, since contemporaneous analyses had established this lower threshold to be compatible with normal male fertility (Cooper et al., 2010). The men treated in this study therefore had a lower initial sperm concentration compared with all previous studies. Interestingly, recovery was slightly delayed, with the median time to recovery to this lower threshold being approximately 6.5 months. This delay is consistent with the earlier integrated analysis which showed slower recovery to either a sperm concentration of either 10 or 20 million/mL, with lower initial sperm concentration. The extent of recovery was also compatible with the earlier integrated analyses since all participants, except 8, recovered by 12 months, and another 5 by 18 months. One participant did not recover even after 4 years, but sperm concentrations were not

^dRecovery to 15 M/mL, not 20 M/mL.

^eDoes not include one pregnancy by a man other than the partner.

^fTestosterone implant 800 mg every 4 or 6 months with depot medroxyprogesterone acetate 300 mg every 3 months.

^gOne of the twins was born with Vater Anomalad, which was thought to be unrelated to the study drug.

^hTestosterone implant 800 mg or 1200 mg every 3 months with or without finasteride.

reported, so it is not known whether he remained severely oligozoospermic which could suggest an intercurrent sterilizing disorder, or had values that were closer to 13–15 million/mL which could suggest regression to the mean.

Together these new data from three large trials verify the earlier analyses that concluded that it is reasonable to expect full recovery of spermatogenesis to levels consistent with normal male fertility, and that the rate of recovery is dependent upon treatment duration and initial sperm concentration. Documented non-recovery of sperm output has been reported in only three men from over 2000 men enrolled in MHC trials (Turner et al., 2003; Gu et al., 2009; Behre et al., 2016). Of these three men, an intercurrent and unrelated sterilizing process, rather than any lasting adverse effect of MHC, was more likely to be the true cause: myotonic dystrophy in one man (Turner et al., 2003) and bilateral epididymitis in another (Gu et al., 2009). In the third man, important details regarding his final sperm concentration were not reported (Behre et al., 2016). Important limitations are that few data of MHC are available for men of African or Hispanic origin, or in subfertile men. Another limitation is that systematic studies of sperm recovery after long-term treatment of eugonadal men with androgens or androgen-progestins for contraceptive or non-contraceptive purposes are not available. Case reports do however suggest that sperm quality tends to recover spontaneously within 4–12 months of cessation of high dose androgens in long-term anabolic steroid abusers.

Actual pregnancies and live births have also been observed in couples after cessation of MHC. Specifically, all couples known to be actively seeking parenthood have reportedly been able to do so, and 51 pregnancies resulting in 32 live births have been identified (Table 2). A limitation of this analysis is that many couples were likely using other forms of contraception after cessation of MHC if parenthood was still not desired, and long term follow up of subsequent fertility was not systematically obtained.

Safety of MHC

Pregnancy outcomes occurring during or after MHC treatment suggest no increase in fetal miscarriage rates or congenital malformations (Table 2). Altogether, 118 pregnancies were reported which resulted in 50 live births, 7 spontaneous abortions, 18 induced abortions, and 1 congenital malformation. Fetal outcomes from the remaining 42 pregnancies were not reported. This corresponds with spontaneous miscarriage rates of 6% (95%CI 2%–12%) assuming no miscarriages amongst pregnancies with unknown outcomes. These miscarriage rates overlap with spontaneous abortion rates of 8%–20% in the general population. The aggregate congenital malformation rate was 0.9% (95%CI 0.0%–4.6%) assuming no malformations amongst pregnancies with unknown outcomes. Accordingly, these data are also consistent with, but are insufficiently powered to exclude the possibility of an increase over the 4% congenital malformation rate in the general population.

A recent methodological advance has been to conduct a randomized placebo controlled androgen-progestin MHC trial from which short-term adverse events due to active treatment could be defined for the first time (Mommers et al., 2008). Almost all men on either active (93%) or placebo (81%) therapy self-reported at least one adverse event, which was mild in severity in almost all cases. However, men receiving active treatment complained twice as frequently than those receiving placebo for certain adverse events: 20% versus 8%, on average for mood and libidinal changes, weight gain, acne and night sweats. These complaints were statistically more prevalent in those treated with active, were generally mild but occasionally led to subject discontinuation (Mommers et al., 2008). Many factors, particularly biochemical factors, were considered clinically irrelevant. Total and high density lipoprotein cholesterol both fell by about 10%, and none of the lipid changes in any treatment or placebo group were statistically significant.

Despite or possibly because of these findings, a recent androgen-progestin MHC efficacy study was prematurely stopped due to concerns regarding mood changes, depression, pain at injection site and increased libido, even though the independent data and safety monitoring board charged with directly overseeing this study found that all criteria for continuation had been met after reviewing the same adverse event data (Behre et al., 2016). Most of these adverse events were mild in severity, only 20 men actually discontinued due to these complaints, and to the contrary, participants themselves reported high levels of satisfaction with the method. Self-reported mood changes and depression in particular, were highly variable across study sites, suggesting interaction with non-drug related factors. Furthermore, depression and mood were only self-reported, and not systematically verified using validated instruments.

In women, the mood changes that occur with estrogen-progestin contraceptives have been attributed to the progestin, and this could also be true for the mood changes reported in both of these androgen-progestin MHC studies. Activation of the gamma-aminobutyric acid type A receptor, which is believed to be important for these mood changes, is also different depending on specific progestins and how they are metabolized. Accordingly, certain progestins could have minimal or no mood problems, but this requires verification. Ultimately, postmarketing surveillance of specific androgen-progestin regimens will be required to properly assess infrequently occurring adverse events. Determining long-term adverse cardiovascular or prostate effects of MHC will also likely require phase four studies since MHC will be most used by younger men in whom the background incidence of either cardiovascular or prostate disease is very low (Piotrowska et al., 2016). It may be that some couples will be willing to accept the theoretical risk of MHC, if the benefits of such therapy in the context of all available options are well-defined. In older men with age-related partial androgen deficiency, for example, lingering concerns regarding the cardiovascular or prostate safety of testosterone therapy remain, yet many men choose to be treated.

Non-hormonal Male Contraception

In contrast to hormonal methods where large-scale multicenter pivotal trials necessary for drug registration by the Food and Drug Administration in the United States are due to start by 2018, the majority of potential non-hormonal male-directed methods are yet

to be tested in humans (Page et al., 2008). Nevertheless, promising targets in the testis, epididymis, sperm, and sperm-egg interaction that appear to be specific and necessary for spermatogenesis, and/or fertilization have been identified. Drugs that can act reversibly and solely on these targets should have few or no systemic adverse effects if these targets are truly specific to spermatogenesis. Despite promising nonclinical preliminary work, all of the few compounds tested in humans thus far have not met these criteria, thereby illustrating the challenges inherent in developing a non-hormonal contraceptive. Gossypol and triptolide, for example, resulted in irreversible infertility. The bis-(dichloroacetyl)-diamines that have been developed thus far to inhibit aldehyde dehydrogenase 1A2, have also inhibited liver aldehyde dehydrogenase thereby causing unacceptable disulfiram-like reactions when co-administered with alcohol. Aldehyde dehydrogenase 1A2 is specific to the testis, and crucial for the conversion of retinaldehyde to retinoic acid, and blocking retinoic acid production in the testis prevents spermatogonial differentiation through suppression of STRA8. The challenge has been developing compounds that specifically inhibit the Aldehyde dehydrogenase 1A2 isoform present only in the testis. A fourth compound, miglustat, induced reversible infertility by inhibiting glycosphingolipid biosynthesis and sperm motility in mice, but miglustat did not alter spermatogenesis in humans. This illustrates that species differences in spermatogenesis exist, and further complicates the development of specific, reversible nonhormonal methods in humans.

Promising testicular targets include bromodomain testis-specific protein-1, which is critical for chromatin remodeling during spermatogenesis, and retinoic acid receptors, activation of which is required for spermatogonial differentiation. Epididymal targets include the epididymal G-protein coupled receptor HE6, which is responsible for reabsorption of tubular fluid, and therefore the sperm microenvironment. Other sperm targets include: epididymal protease inhibitor (EPPIN) which prevents binding of semenogelin 1, a semen coagulation protein, and therefore prevents impaired sperm motility, and; voltage-gated calcium-permeable ion channels (CatSper), which are important for sperm hyperactivation and motility.

Developing drugs that act on these or other targets would eventually require scalable drug synthesis, stability, and microbial testing, and certification of good manufacturing practice standards. Academic researchers are ill-equipped to meet the regulatory hurdles required for such an undertaking, and hence the National Institute of Child Health and Development has established the male Contraceptive Clinical Trials Network to implement late phase 2 and phase 3 studies for drug registration purposes, and assist in partnering with pharmaceutical industry. Currently this network has focused on hormonal methods. However, the extensive clinical trial experience developed for male hormonal contraceptive methods will be applicable for the testing of non-hormonal approaches, once suitable phase 1 and 2 studies of compounds directed to these targets have been performed.

Summary and Conclusions

Male-directed contraceptive methods are estimated to be worth 40–200 billion dollars worldwide, assuming a market size of 10 million in United States and 50 million worldwide. Many couples already depend upon less than ideal male-directed methods, and there is large unmet need to develop better methods. Despite this, many hurdles remain. Despite this, MHC is the closest to regulatory approval from a drug registration perspective. As discussed, much progress has been made in delineating the effectiveness, reversibility and short-term safety of MHC. Remaining uncertainties include whether such methods can be universally used by all men, how to prevent, predict or monitor sperm rebound, and whether clinically relevant and diagnosable mood changes actually occur, and if it does occur, whether these can be minimized with progestins with optimal characteristics. Fully characterizing the long-term prostate and cardiovascular safety will require post-marketing surveillance, but the low incidence of these disorders in young men provides some reassurance that the absolute risk with MHC is likely to be small. No single female or male directed method will be ideal for all couples at all times, and hence the priority should be to broaden choice to reduce unintended pregnancies, and the individual, family, and societal sequelae that are associated with unintended pregnancies. Male-directed hormonal and non-hormonal methods promise to allow both partners to share equally in family planning responsibilities.

COMPARATIVE MAMMALIAN MALE REPRODUCTION

Mammalian Reproduction Overview

William Vincent Holt, University of Sheffield, Sheffield, United Kingdom

Glossary

Altricial Offspring that are hatched or born in a very immature and helpless condition so as to require parental care for some time.

Delayed implantation Delayed implantation or embryonic diapause is a reproductive strategy used by approximately 100 different mammals in seven or eight different orders. In embryonic diapause, the embryo (blastocyst) does not immediately implant in the uterus after sexual reproduction has created the zygote, but is maintained in a state of dormancy.

Eutheria Is the taxonomic name for the main group of living mammals. This taxon contains the placental mammals, of which humans are one species.

Marsupials Mammals of an order whose members are born incompletely developed (i.e., altricial) and are typically carried and suckled in a pouch on the mother's belly. Marsupials are found chiefly in Australia and New Guinea, and also in America.

Metatheria Is a mammalian clade that includes all mammals more closely related to marsupials than to placentals. It is a slightly more inclusive group than the marsupials; it contains all of the living mammals with abdominal pouches (most female marsupials) as well as their more primitive ancestors and relatives.

Monotreme Any member of the Monotremata, the most primitive order of mammals, characterized by certain birdlike and reptilian features, such as hatching young from eggs, and having a single opening for the digestive, urinary, and genital organs. Platypus and echidnas are the only extant monotremes.

Phylogeny The evolutionary history of a group of organisms, especially as depicted in a family tree.

Prototherian Primitive oviparous mammals belonging to the order Monotremata.

Introduction

The diversity of reproductive strategies and mechanisms exhibited by mammals is bewildering and complex. This is not surprising as there are estimated to be more than 5400 species of mammals worldwide (Wilson and Reeder, 2005), subdivided into 1229 genera (groups of species that are highly related and share common phylogeny). These species have evolved to occupy multiple ecological niches, and therefore exhibit a huge amount of life history variation. Detailed evolutionary studies of mammalian origins have produced some contentious outcomes, partly because phylogenetic trees can be derived using both DNA and protein sequences, as well as paleobiological data interpreted by a diverse array of statistical approaches. However, a relatively recent publication in Science (Meredith *et al.*, 2011) presented a credible attempt to reconcile these divergent views and these authors published a helpful mammalian phylogeny based on data from 164 species.

As a group, mammals are distinguished from other species by their ability to support their newborn offspring with milk, which is produced by the female's mammary glands during lactation. Milk is a rich source of important nutrients, including fatty acids, proteins, vitamins and growth factors, but it also provides newborns with a range of important immunologically active compounds that protect against infections during early postnatal development (Blum and Baumrucker, 2008; Oguchi *et al.*, 1997). Lactation is thought to be an ancient process that evolved in a clade of amniotes (synapsids, or mammal-like reptiles (Kemp, 2007)) which may have existed before the first appearance of mammals on earth (Ofstedal, 2012). Owing to its important role in neonatal development, lactation has persisted in all forms of mammals, but the interactions between mothers and their offspring are highly variable between species. Monotremes (prototheria), i.e., platypus and echidnas, are the only egg laying mammals and yet their neonates still receive milk from their mothers. Likewise, the marsupials (metatheria), whose neonates are still in a fetal and poorly developed condition (altricial) when born are provided with milk for prolonged periods after birth. The placental mammals (eutheria), which constitute the overwhelming majority of mammalian species, despite having evolved placental function to support their offspring during embryonic and fetal growth, still lactate and thus provide their neonates with an important additional source of nutrition in early life. These differences, based on the various ways in which neonates are supported during early postnatal growth, represent a useful criterion for dividing the mammals into three distinct classes with different evolutionary histories. It is, therefore, worth beginning this review by making some general observations about the reproductive mechanisms that characterise these three mammalian groups.

Monotremes

The four extant species of echidna within the order *Tachyglossidae*, together with the duck-billed platypus (*Ornithorhynchus anatinus*) are the egg laying mammals, and show many reproductive characteristics reminiscent of birds and reptiles. These species are geographically restricted and occupy different habitats; echidnas are terrestrial mammals and are found only in Australia and New Guinea while platypus are aquatic, living in the river systems of eastern Australia and Tasmania. Genome research has suggested that monotremes diverged from the other mammalian lineage (therian mammals; which later further diverged, forming the marsupials and the placental mammals) about 166 million years ago. Detailed studies of platypus and echidna reproductive biology have only been conducted over the last few decades (see, e.g., [Grant and Temple-Smith, 1998](#); [Morrow and Nicol, 2009](#)) and given that these species are secretive and until recently ([Wallage et al., 2015](#)) have not been easy to breed in captivity, knowledge about their general biology is still rather rudimentary ([Johnston and Keeley, 2015](#)). In fact, some aspects of their biology seemed highly improbable to earlier generations of scientists, and indeed, when the first description of a platypus was sent to the Royal Society in London in the early 19th century ([Home, 1802](#)), it was widely regarded as a hoax!

Echidnas and the platypus are both seasonal breeders, and it is worth noting here that seasonality is an important reproductive adaptation for many, if not most, mammals. For detailed information on comparative mammalian reproductive biology the reader should consult the encyclopaedic book by Asdell entitled "Patterns in mammalian reproduction" ([Asdell, 1965](#)) and a subsequent revision of the same book, which presents further detailed information ([Hayssen, 1993](#)). The monotremes are testicond mammals, which means that the males' testes are situated inside the body cavity, rather than in a scrotum. The spermatozoa are filiform and bear more resemblance to avian and reptilian spermatozoa than to spermatozoa of other mammals; during sperm maturation in the epididymis, the spermatozoa become organized into bundles of approximately 100 cells, which swim together in synchrony. The microanatomy of the epididymis has been likened to that of birds and reptiles ([Bedford and Rifkin, 1979](#); [Carrick and Hughes, 1982](#)). Monotreme yolky oocytes are fertilized within the female's oviduct where they meet the spermatozoa ([Grutzner et al., 2008](#)). It is also worth noting that, as with marsupials (with the exception of some planigales), and, unlike eutherian mammals, the amino acid sequence of protamine 1 of monotreme spermatozoa does not include cysteine residues ([Retief et al., 1993](#)). The sperm heads are thus considered rather fragile as there is no capacity for the formation of stable crosslinked nuclear protein-DNA complexes. Presumably platypus and echidna spermatozoa typically ascend the female tract as motile bundles ([Johnston et al., 2007](#); [Nixon et al., 2016](#)), and although relatively little is known about fertilization mechanisms, it is interesting to see that the platypus genome encodes each of the four proteins of the human zona pellucida. Field and captive observations of echidna reproduction ([Nicol and Andersen, 2007](#); [Rismiller and McKelvey, 1996](#)) have shown that the egg is incubated in the pouch for approximately 10 days after a pregnancy of about 3 weeks, whereupon the female eventually deposits the young in a nursery burrow. As neither the platypus nor the echidna possess nipples, the offspring suckle directly from mammary lobules that empty into an invagination of skin surrounding a hair follicle ([Grant and Temple-Smith, 1998](#)).

Remarkably, it appears that only the left side of the female platypus reproductive tract is functional, while that of the echidna has two functional ovaries. The male echidna does not urinate through the penis, but via urogenital papillae. The echidna penis itself is most bizarre, being about a quarter of the animal's body length when erect and terminating in two sides, each side possessing a glans penis taking the form of 2 rosettes. The urethrae terminate on the surfaces of the rosette in a series of openings through which the semen emerges ([Johnston et al., 2007](#)); the platypus penis is equally bizarre and appears adapted for securing this organ into the urogenital sinus of the female during mating, which occurs in the water column.

Marsupials

Recent genomic data ([Nilsson et al., 2010](#); [Warren et al., 2008](#)) suggest that marsupials diverged from eutherian mammals 130–150 million years ago, and since then they have colonised both central and south America as well as Australia and New Guinea. The marsupials, which include about 330 extant species, show huge variation in terms of their ecology and reproductive characteristics. This remarkable diversity is, however, often underestimated by those not familiar with the group as a whole ([Johnston and Keeley, 2015](#); [Johnston and Holt, 2001](#); [Tyndale-Biscoe and Renfree, 1987](#)). In contrast to the popular belief that all marsupials possess a pouch and lack a placenta, some of the carnivorous dasyurid species (e.g., phascogales and antechinus) possess only a marginal pouch that does not cover the mammary area, while the Peramelidae family (e.g., bandicoots) even develop an invasive chorioallantoic placenta during pregnancy. The majority of marsupials are also seasonal breeders, and some species, including macropods (kangaroos and wallabies) and the honey possum ([Oates et al., 2007](#); [Renfree, 1981](#)), exhibit embryonic diapause, where the embryo remains in the uterus for up to several months without showing any development; development can be rapidly initiated by changes in day length or the loss of pouch young. The occurrence of embryonic diapause is not restricted to marsupials as it has also been recognized in a range of eutherian mammals ([Mead, 1993](#)) as a strategy for the temporal separation of mating events and subsequent embryonic development. While it is impossible to describe in this short review how reproductive systems vary between marsupials, it is worthwhile attempting to summarise a few key differences, as well as emphasising how some of their characteristics differ from eutherian mammals.

Reproductive Features of Marsupials

Species diversity among marsupials is as multifaceted as diversity among eutherian mammals. Some species, such as the Tasmanian devil (*Sarcophilus harrisii*), which is the largest of the dasyurids, are carnivorous, while others, such as the macropodidae are herbivores. Marsupials have also evolved multiple and diverse reproductive strategies and as a consequence the details of their reproductive biology are also highly varied. In an effort to classify and make sense of the different reproductive strategies found among marsupials, Tyndale-Biscoe and Renfree (1987) proposed that four distinct categories could be identified. However, because more knowledge of marsupial reproduction and its complexity has become available over the last 30 years, this simple classification needed further refinement (Johnston and Keeley, 2015).

Understanding reproductive anatomy in female marsupials is also challenging in itself, being different from that of the eutherian mammals (Fig. 1(D)). The caudal region of the female reproductive tract possesses two lateral vaginae, each of which opens into a urogenital sinus that also receives the urethra (Tyndale-Biscoe and Renfree, 1987). The differences arise during organogenesis owing to a difference in the migration of the embryonic urinary and genital ducts. The ureters pass medially to the Wolffian and Mullerian ducts, rather than laterally to them, as in eutherians. As a result, the female Mullerian ducts are prevented from fusing medially so that the uteri and vaginae on either side remain separate, except where the ducts fuse medially at the junction of the developing uterine and vaginal sections (Mackay *et al.*, 2004; Renfree *et al.*, 1996).

Prior to parturition, it is thought that most marsupials develop a new birth canal; this joins the posterior margins of the vaginal cul-de-sac to the anterior end of the urogenital sinus (Johnston and Keeley, 2015). In most species that have been examined, the connective tissue closes and repairs quite rapidly while in others (e.g., Honey possum, kangaroos and wallabies) it remains patent.

At the time of copulation, semen is deposited into the cranial portion of the urogenital sinus, from where it moves through the lateral vaginae, a vaginal complex or cul-de-sac, cervix and into separate uteri and oviducts. Although this is the general scheme, there is considerable anatomical variation between and within species (Tyndale-Biscoe and Renfree, 1987), which sets considerable challenges to the development of artificial insemination and embryo transfer technologies, where both semen and embryo deposition require both anatomical and temporal precision.

Inter-male competition is prevalent in many species, for example, wallabies (Jarman, 1991) and some researchers have used testis weight as a predictor of this reproductive strategy; in principle, it is likely that species engaging in male-male competition would benefit from high sperm production capacity and hence a high testis/body weight ratio (Rose *et al.*, 1997). Some species, especially the dasyuridae, combine such competitiveness with a more complex phenomenon known as semelparity (Naylor *et al.*, 2008). This strategy involves the almost complete death and ecological disappearance of males after mating combined with a heavy reliance on sperm storage in oviductal crypts within the female reproductive tract (Taggart *et al.*, 1999; Taggart and Temple-Smith, 1991).

The morphology and physiology of marsupial spermatozoa are highly variable between species (Breed, 1994), but it is notable that sperm morphology within a single species can either be highly pleiomorphic, as in the koala (*Phascolarctos cinereus*), or show very little variability (e.g., macropodidae). The new world marsupials have evolved an unusual reproductive specialization whereby their spermatozoa become “paired” during maturation in the epididymis (Krause and Cutts, 1979; Temple-Smith and Bedford, 1980); the pairing involves very specific and stable interactions between the flattened surfaces of the two sperm heads, and the end result appears to provide both of the spermatozoa with synchronized and rapid motility (Moore and Taggart, 1995; Taggart *et al.*, 1993). Experiments (Rodger and Bedford, 1982) have shown that the two spermatozoa become separated shortly before meeting the egg, but detailed studies of marsupial sperm capacitation and acrosome reaction have yet to be conducted.

The variations in spermiogenesis and epididymal sperm maturation result in significant differences in sperm morphology between marsupials (Rodger and Mate, 1993; Temple-Smith, 1994). These represent wonderful sources of information for researchers interested in the comparative evolution of reproductive biology; however, the relevant literature is far too detailed and rich to describe here. The reader is advised to consult J. M. Bedford’s thought provoking reviews (Bedford, 1996, 2004, 2008, 2014) on gamete form and function.

Fertilization and embryonic development in marsupials show many differences from the same processes in the eutherian mammals; the main points of these differences are well summarized in two excellent reviews (Baggott, 1992; Selwood, 2007). Marsupial oocytes are much larger (150–200 µm diameter) than those of the eutherians (typically about 100 µm diameter), and after fertilization the zygotes exhibit visible polarity as an early indication of embryonic cell commitment. The polarity predicts the eventual separation into two cell types, pluriblast (equivalent to the inner cell mass of the mouse), the trophoblast, and ultimately the alignment of the body axis.

Assisted Reproductive Technologies and Marsupials

Like animal populations everywhere, the unique fauna of Australia is under threat from many directions, including land management, industrial development and environmental pollution, habitat fragmentation, disease and invasive species. Many of the marsupials are therefore endangered and under imminent threat of extinction. However, there are also many conservation schemes that attempt to counter these problems. Almost all of the conservation measures are based around habitat protection and the mitigation of direct threats, but some researchers have argued that these policies should be backed up by the use of assisted reproductive technologies (ART), such as artificial insemination and the cryobanking of genetic resources (Czarny *et al.*, 2009; Johnston and Holt, 2001) that could be used for genetic management. Unfortunately, these technologies are still very underdeveloped with respect to

the marsupials, mainly because there is such a paucity of knowledge about the reproductive physiology of marsupials (Johnston and Holt, 2001). Using ART requires detailed knowledge of both male and female physiology, coupled with practical methods for semen collection, the control of ovarian cycles, semen cryopreservation and reproductive anatomy. All of these factors have proven extremely challenging in marsupials. Having pointed out the difficulties, it is worth mentioning that appropriate investment of effort does indeed produce results, and that artificial insemination has been successful in the koala (Allen *et al.*, 2008; Johnston *et al.*, 2003) and tammar wallaby (Paris *et al.*, 2005; Rodger *et al.*, 2009).

Reproduction in Eutherian Mammals

The eutherians account for the vast majority of extant mammals. Their shared reproductive characteristic is that they are all viviparous; that is, they all produce live offspring that have been nurtured via an invasive chorioallantoic placenta throughout pregnancy. Unlike the marsupials, the newborn offspring reach an advanced stage of development before birth and continue to receive maternal support after birth by suckling milk from the mammary glands. Placental function during pregnancy is supported by the secretion of progesterone, produced initially from the corpus luteum, formed within the ovary when the post-ovulatory Graafian follicle becomes luteinized, and later in many species by the placenta itself. Circulatory progesterone and its metabolites (known collectively as progestagens) can readily be measured after excretion into fecal samples and/or urine. In practical terms this is the basis for the non-invasive detection of oestrous cycles and pregnancy, a technique that can be used with many wild mammalian species (Brown *et al.*, 1994; Burgess *et al.*, 2012; Wasser *et al.*, 1996). Fig. 2 illustrates this principle, using data from a study of the Mohor gazelle (*Gazella dama mhorr*) (Pickard *et al.*, 2001).

One important role of progesterone in eutherian mammals involves transforming the lining of the uterus in order to allow implantation of the early embryo and the subsequent formation of the placenta. Prior to ovulation the ovary has been more concerned with oocyte development within the follicle, a process supported by the production of estradiol from thecal and

Fig. 2 Faecal progestagen concentrations (mean $\pm$ SEM; $n=7$ females) before conception (red triangles), during gestation (blue diamonds) and after parturition (red squares) in the Mohor gazelle (*Gazella dama mhorr*). The first vertical line indicates the date of insemination and the second vertical line indicates the date of parturition. The progestagen concentrations do not increase significantly until about 9 weeks after insemination, whereupon they rise steeply and remain high until shortly before parturition. Reproduced with permission from Pickard, A.R., Abaigar, T., Green, D.I., *et al.*, 2001. Hormonal characterization of the reproductive cycle and pregnancy in the female Mohor gazelle (*Gazella dama mhorr*). Reproduction 122, 571–580.

granulosa cells that line the follicle itself. These two sequential processes, which together result in the basic features of the estrous cycle (follicular and luteal phases), have been moulded by evolutionary processes in ways that are adapted to assure optimal reproductive success in different habitats and climates.

Control of the estrous cycle and its relationships to environmental factors such as photoperiod is exerted via the neuroendocrine system. These physiological processes are governed by the pulsatile secretion of gonadotropin-releasing hormone (GnRH) from nerve endings in the hypothalamus which are then released into portal vessels connected to the anterior pituitary. The pituitary responds by a highly synchronized release of two gonadotropins (luteinizing hormone (LH)) and follicle stimulating hormone (FSH), which together and in association with inhibin and activin from the ovary, control gonadal function (i.e., both in the ovaries and the testes). In some mammals (e.g., human, cattle, pigs) the estrous cycle occurs regularly and spontaneously until it is interrupted by pregnancy, but it is important to note that in many species (e.g., rabbits, ferrets, cats, camelids, often grouped together and known as “induced ovulators”) there are sophisticated control mechanisms that help to ensure either that births occur at a favourable time of year, or that ovulation only takes place when a female is likely to encounter a male. It would, for example, be a waste of energy for females with solitary lifestyles to ovulate regardless of the likelihood of being mated. In many species, ovulation can be induced, often by physical stimulation of the female genitalia during mating, but also by the presence of ovulation-inducing hormones in seminal plasma (e.g., Adams and Ratto, 2013, Camelidae).

Reproduction in mammals is modulated by subtle and sophisticated mechanisms, details of which are beyond the scope of this article. However, it is worth mentioning the relatively recent discovery that the production of leptin, a peptide hormone produced by adipose tissues and also by the placenta, is now seen as an important modulator of diet, body condition and the neural control of reproduction (Barb *et al.*, 2005; Daniel *et al.* 2013; Evans and Anderson, 2017). Extremes of body condition such as obesity or malnutrition are known to impact the success of reproduction in humans and other species (Hausman *et al.*, 2012; Perez-Perez *et al.*, 2015; Walzem and Chen, 2014).

Reproductive Seasonality

Seasonality has a major impact on reproductive processes and many eutherian mammals have adjusted their entire reproductive repertoire accordingly. For example, the breeding season of the harbour porpoise (*Phocaena phocaena*) and common dolphin (*Delphinus delphis*) is restricted to a short period in spring or summer (Neimanis *et al.*, 2000; Westgate and Read, 2006). Testicular weight during the summer months is approximately five times greater than in winter because, while spermatogenesis and sperm production are maximally active during the summer, they cease during winter and the testes undergo regression. Cycles of seasonally activated testicular activity followed by regression also occur in many other mammalian taxonomic groups, including various deer species (Lincoln, 1971), rodents and bats.

Many species align their reproductive physiology with environmental factors so that their offspring are born when environmental conditions are most favourable. Two common tactics for achieving this objective involve introducing a delay between mating and either fertilization itself, or the development and implantation of embryos (for review, see Orr and Zuk, 2014). One approach involves the prolonged storage of spermatozoa in the female reproductive tract (Holt, 2011; Holt and Fazeli, 2016); this is usually limited to several days in mammals, although sperm storage in some bat species can last several months (Krishna and Dominic, 1978; Racey *et al.*, 1987; Roy and Krishna, 2011). An alternative approach to the temporal uncoupling of mating and fetal development, known as delayed implantation (Fenelon *et al.*, 2014; Lopes *et al.*, 2004) has been adopted by at least 130 eutherian mammals. In species such as the seal (Pomeroy, 2011), badger (Yamaguchi *et al.*, 2006), Giant panda (Zhang *et al.*, 2009), armadillo and stoat (reviewed by Mead, 1993), the embryos do not develop for some weeks or even months, before the diapause ends and the pregnancy resumes. Sixteen species of mustelids exhibit long gestations ranging from 172 to 365 days, with embryonic development being arrested for most of this period (Mead, 1993). In these species, the fertilized embryo remains within the uterus until an external signal such as shortening day length stimulates the embryo to resume its development and undergo implantation. Mead (1993) pointed out that the distribution of this trait within a genus is not constant, and cited long-tailed weasels and stoats (*Mustela frenata* and *Mustela erminea*) as examples; these species exhibit delayed implantation, whereas the least weasel (*Mustela rixosa*) does not. Eastern and western spotted skunks (*Spilogale putorius*) may be even more closely related, yet only those from west of the continental divide exhibit embryonic diapause.

Mechanisms for the control of embryonic diapause in mammals are usually classified as either “facultative” or “obligate” (Fenelon *et al.*, 2014). Facultative diapause is induced by the metabolic stress of lactation, and implantation occurs when the stress is relieved. Examples include some of the marsupials, where the diapause is terminated immediately if lactation ceases (Renfree, 1981). Obligate diapause is widespread among the mustelidae as described above (Mead, 1993), is rigidly controlled by factors such as photoperiod and occurs in every gestation. One of the mustelid species (the stoat, *Mustela erminea*) employs obligate embryonic diapause in a very unusual way. Reproductive activity in this species, which is highly seasonal, involves the young female stoat reaching sexual maturity at about 6–8 weeks of age; she is mated while still in the nest and before she is weaned (Gulamhusein and Tam, 1974). Mating takes place in June or July, but the female does not give birth until the following April or May; in this instance, the delay of implantation is almost certainly necessary to ensure that the female is sufficiently mature to bear the stress of pregnancy.

Intriguingly, such observations of reproductive heterogeneity among closely related species tend to suggest that the mechanisms governing embryonic diapause and delayed implantation evolved independently. Using similar arguments, evidence that sperm storage mechanisms also show considerable dissimilarity between species leads towards the same conclusion (Holt and Lloyd, 2010). It seems reasonable to suggest that neither long-term sperm storage nor embryonic diapause required drastic genomic

and metabolic reorganization during evolution in order to introduce these reproductive modifications. Recent research on the expression and function of microRNA, short RNA molecules that are increasingly recognized as being significant regulators of development, suggests that they have an important role in controlling delayed implantation and embryonic diapause (Su *et al.*, 2010). This significant example of epigenetic regulation might explain how functionally important and highly targeted physiological differences could evolve so rapidly in closely related species.

Reproductive Adaptations in Eutherian Mammals

Evolution has led to a few unusual reproductive outcomes for eutherian mammals, and rather than try to provide here a detailed description of basic mammalian reproductive biology, which can be found in textbooks and reviews (Bronson, 1989; Doty, 1976), it is more interesting to point out how groups of species have adapted their reproductive patterns and physiologies to suit their specific needs. Eutherian mammals have colonized multiple habitats all over the world, and have evolved a dazzling variety of reproductive strategies and physiological mechanisms. Some species live in social groups while others are mainly solitary; some are tropical and others live in high latitudes where they have to cope with highly seasonal environments with differing day lengths, ambient temperatures, varying amounts of rainfall and availability of food.

African mole rats belong to a family of about 18 species of rodents whose lifestyle is, as their name suggests, mainly subterranean, and have evolved a very unusual social system that bears more similarity to that of bees and other social insects, than those of other mammals (Faulkes and Bennett, 2001). About 14 of these species live in socially well-organized colonies, where individuals within the colony have to fulfil specific functional roles such as foraging, digging tunnels or defending the colony. The ability to breed is restricted to a very small group of individuals, which includes a single female or “queen” and two or three breeding males. All other members of the colony are reproductively suppressed; consequently there is a high level of inbreeding within colonies (Reeve *et al.*, 1990). When a queen dies, one of the other females can take her place, thus showing that reproductive suppression is not irreversible. The non-reproductive males possess testes and produce spermatozoa, but they do not attempt to mate with the non-breeding females. In addition, species such as the Damaraland High Veldt mole rat *Cryptomys hottentotus pretoriae* (Rensburg *et al.*, 2002), are seasonal breeders, thus showing a rich repertoire of reproductive adaptations that provide a wealth of material for researchers interested in reproductive control mechanisms. This is not the only example of cooperative breeding in mammals; it also happens in some primates such as marmosets (*Callithrix jacchus*) (Mattle *et al.*, 2008; Yamamoto *et al.*, 2014; Ziegler, 2013), where a dominant female can suppress the reproductive capacity of other females in the group, as well as in canids (Moehlman and Hofer, 1996), beavers, mongooses and porcupines (for review, see Lukas and Clutton-Brock, 2012).

As pointed out more than four decades ago by Weir and Rowlands (1973), there are few, if any, reproductive mechanisms whose evolution can be directly attributed to either habitat or taxonomy. These authors based their argument on the premise that if two species of a genus are found to be different in any respect, then that particular factor is not a generic characteristic. This complicates our understanding of mammalian reproductive evolution and implies that some traits, such as delayed implantation and sperm storage in the female tract, have evolved independently several times. This possibility holds some promise for the survival of mammals in the face of current changes in climate and other environmental challenges as it indicates that they can adapt quickly when conditions change. In a review that was directed at considering the likely impacts of climate change, Bronson (2009) predicted that small rodents will probably adapt to new conditions with relative ease because of their short generation time; however, he also cautioned that large and long-lived species whose reproduction is rigidly controlled by photoperiod will find it more difficult to adapt, especially as they might shift their geographical ranges.

Conclusions

This short review emphasises that mammalian reproduction owes its widespread success largely to the way that a few physiological processes such as sperm production, ovulation and embryonic development have developed within a framework that can be modified by the demands of habitats. While the detailed neural mechanisms controlling the endocrine system, the cell biology of sperm formation or early embryonic development can be studied in isolation using experimental animals, a comparative overview between species demonstrates that nature has treated these fundamental processes as reproductive building blocks that can be engineered together in an endless number of permutations and combinations. That these permutations characterize the whole animal is a feature of biology that is frequently overlooked in an era when research tends to focus mainly on gene and protein sequences, without necessarily remembering that a mouse or rat is not the same as an elephant. This principle has been succinctly stated as “a cow is not the same as a cheetah” in numerous lectures and reviews by Wildt *et al.* (2001) of the Smithsonian Conservation Biology Institute, Centre for Species Survival in Washington, DC, United States.

Glossary

Blood Testis Barrier (BTB) This is a junctional complex between adjacent Sertoli cells in the seminiferous tubule.

Bull A male bovine.

Genomic selection This is genetic selection based on analysis of a bull's DNA.

Leydig cells These cells are just outside of the seminiferous tubule and produce the male hormone testosterone.

Prepuce The tissue that covers the penis when the penis is not erect.

Primary spermatocyte This is a cell produced by mitosis of a spermatogonia but will enter into meiosis.

Round spermatid This is the final cell of meiosis in the male and comes from the secondary spermatocyte.

Secondary spermatocyte This is the second cell in meiosis and is produced by the primary spermatocyte.

Seminiferous tubule This is where sperm production occurs within the testis.

Sertoli cells A nurse cell for the developing male germ cells that become sperm.

Spermatogonia These are the germ cells in the male that undergo mitosis.

Testicular parenchyma The tissue in the testis in which the seminiferous tubules are located.

Testis The organ of the male that produces the male germ cells.

Introduction

Cattle belong to the family Bovidae and genus *Bos*. There are two subspecies of cattle, *Bos taurus* and *Bos indicus* however many breeds exist within each of the subspecies and include both meat, milking and dual purpose. In addition, some cattle are also used as beast's burden. This article will focus on reproduction of male cattle. Comparisons of *B. taurus* and *B. indicus* will be made as appropriate.

Anatomy of the Bull Testis

The development of germ cells occurs in the testis which is suspended vertically in the bull and located within the scrotum. The testicular parenchyma is composed of seminiferous tubules that connect to the rete testis in mediastinum and the interstitial space composed of Leydig cells, blood vessels, lymphatic vessels and nerves (Senger, 2012). The germ cells undergo mitosis and meiosis in the seminiferous tubules (Amann and Schanbacher, 1983; Amann, 1983) which both begin and end at the rete testis. The average bull testis contains 5.2 km (3.2 mi) of seminiferous tubules (Lennox and Logue, 1979). In the basic anatomy and physiology there are only minor differences between domestic cattle of the *B. taurus* and *B. indicus* subspecies. While *B. taurus* is adapted to temperate climates, *B. indicus* is adapted to warm climates and this reflects on how the subspecies differ in temperature regulation of the testes (Brito *et al.*, 2004).

Spermatogenesis

Spermatogenesis in the bull consists of proliferative (mitosis, spermatocytogenesis), meiotic (meiosis) and differentiation (spermiogenesis) phases (Courot *et al.*, 1970; Amann, 1983). The proliferative phase consists of mitotic division in which germ cells numbers increase but also differentiate through Type A1-A3, Intermediate and B1-B2 spermatogonia, ending in the formation of primary spermatocytes. The next phase is meiosis in which the DNA complement undergoes reduction and division from the diploid (2N) to the haploid (N) state. The cell types go from the primary spermatocyte (2N) to the secondary spermatocyte to the round spermatid (N). The round spermatid then undergoes a differentiation into the spermatozoa by elongation of the nucleus, growth of the axoneme and tail, formation of the mitochondria and the acrosome among other changes needed for a sperm to be motile and deliver its haploid DNA to the oocyte at fertilization. In theory, spermatogenesis in the bull can produce up to 256 spermatozoa from each type A1 spermatogonium that enters into the proliferating pool of germ cells. Some authors (Amann and Schanbacher, 1983) have suggested there may be fewer mitotic division and only 64 spermatozoa result but the higher number is now accepted for almost all mammals. However, as will be described below this theoretical maximum number is never reached.

While the developing germ cells undergo the process of spermatogenesis they are surrounded by Sertoli cells that serve to support and direct the division of the germ cells. The Sertoli cells fill the seminiferous tubules extending from the basement membrane to the lumen and interacting with adjacent Sertoli cells via junctional complexes including tight junctions known collectively as the blood

Fig. 1 A bull seminiferous tubule. The seminiferous tubule is the large circular structure in the image. Outside the seminiferous tubule are the Leydig cells that produce testosterone. From the outside towards the center of the seminiferous tubule the following cell types are visible: spermatogonia, primary spermatocytes, and round spermatids. Importantly, multiple types of germ cells can be seen within the tubule at any point in time.

testis barrier (BTB). The BTB allows the formation of the basal, adluminal, and luminal compartments (Amann, 1983; Cheng and Mruk, 2012). Cells in the basal compartment communicate with the interstitial compartment. Cells in this compartment are the Type A, I, B spermatogonia and the primary spermatocytes all of which undergo mitosis during the proliferative phase. The adluminal compartment is toward the lumen of the seminiferous tubule and beyond the BTB. In this compartment, substances reaching the developing germ cells must first pass through the Sertoli cells and thus Sertoli cells manipulate the environment so that meiosis and differentiation can occur to primary, secondary spermatocytes, round spermatids and elongating spermatids developing into spermatozoa. The spermatozoa are finally released into the lumen at the end of spermatogenesis in a process known as spermiation. An actual seminiferous tubule from a bull is shown in Fig. 1 and demonstrates how multiple germ cell types are present at the same time in a seminiferous tubule.

Unique to germ cell division in the male is the retention of cytoplasmic bridges between a cohort of germ cells developing from a single Type A spermatogonium and likely sharing plasma membrane components. The plasma membranes of X and Y bearing sperm are thus unlikely to have any differences and have never been shown to have such differences in the bull. Many germ cells also undergo the process of programmed cell death, apoptosis, although the frequency can increase due to disease, environmental heat exposure, or stress. We routinely find lower levels of germ cells than theoretically possible. For example, in Holstein bulls we found a mitotic yield of 8.9 ± 1.3 primary spermatocytes per A spermatogonia (theoretical max=64); a meiotic yield of 1.7 ± 0.2 round spermatids per primary spermatocyte (theoretical max=4); a spermatogenic yield of 17.1 ± 0.9 round spermatids per A spermatogonia (theoretical max=256). Loss of germ cells thus occur both in mitosis as well as meiosis although the largest number are lost in mitosis. Why so many germ cells die is unclear but may be a reserve ability of the male to recover from testicular environmental or physical damage. A single cohort of germ cells is also interacting with only 1 Sertoli cell. However due to the staggered nature of stages and cycles (Senger, 2012), a single Sertoli cell needs to coordinate germ cells going through mitosis, meiosis and differentiation at the same time.

Endocrinology of the Bull and Puberty

The endocrinology of the adult testis has been reviewed by Amann (1983) and is shown in Fig. 2. In the adult bull, production of GnRH comes from the hypothalamus which causes the production of LH and FSH from the anterior pituitary gland. The LH causes Leydig cells to produce testosterone which supports function of Sertoli cells, germ cells and binds to androgen binding protein in the seminiferous tubules to be carried down to the epididymis via seminiferous tubule fluid. Testosterone also enters the blood stream and acts via negative feedback to regulate GnRH and LH secretion. The FSH released from the anterior pituitary causes the Sertoli cells to convert testosterone to estradiol, produce inhibin, androgen binding protein and formation of the blood testis barrier. The estradiol and inhibin produced from Sertoli cells feedback on the anterior pituitary and hypothalamus in a negative feedback loop to regulate FSH.

Prior to birth the structures of the testis and endocrinology of the male is very different. The primordial germ cells migrate into the progenitors of the seminiferous tubules, the primary sex chords and differentiate as gonocytes. The Pre-Sertoli cells also migrate into the primary sex chords leaving fetal Leydig and stromal cells in the remaining tissue of the developing testis. Endocrinology in

Fig. 2 Endocrinology of the adult bull. The hormones depicted are gonadotropin releasing hormone (GnRH), luteinizing hormone (LH), follicular stimulating hormone (FSH), estradiol (E₂), testosterone (T), and inhibin. Peripheral circulation is depicted as blood vessels into which T, E₂ or inhibin may diffuse. The impact of LH is on Leydig Cells and FSH on Sertoli cells. The tight junctions are indicated as TJ in the diagram. Androgen binding protein (ABP) is produced by the Sertoli cells and remains in the seminiferous tubules and binds T, which is then carried down in the seminiferous tubule fluid to the epididymis (Epid.). Based on work from Amann (1983).

the fetus is very different than the adult. At this point the Fetal Leydig cells secrete testosterone equal to amounts secreted in the adult however this secretion is independent of LH. The testosterone has a major function in the development of the primitive male reproductive tract, the Wolfian ducts. The Pre-Sertoli cells are secreting anti-mullerian hormone which leads to regression of the primitive female reproductive tract known as the Mullerian duct. The testosterone also is converted to estradiol and is secreted into general vascular circulation. Events in the bull from birth to puberty have been reviewed by Rawlings *et al.* (2008). Prior to birth the production of testosterone from fetal leydig cells decreases and fetal leydig cells degenerate by 8 weeks of age. At approximately 4 weeks of age the adult Leydig cells begin developing and respond to LH and produce testosterone that drives mitosis and maturation of Sertoli cells from 4–20 weeks of age with complete maturation of adult Sertoli cells by 30–40 weeks of age. Primary spermatocytes form by 20 weeks of age, secondary spermatocytes from 20–30 weeks of age, round spermatids from 25–30 weeks of age and elongated spermatids from 25–35 weeks of age, with mature spermatozoa forming from 32–40 weeks of age.

There is a gradual increase in production of sperm at the time of puberty so there is a need to define puberty in order to make comparisons of treatments or procedures that might alter the timing of puberty. Puberty has therefore been defined in the Holstein bull as when scrotal circumference is >28 cm, or there are more than 50×10^6 sperm/mL in the ejaculate with >10% progressively motile sperm (Amann, 1983). These are intended to be a measure when puberty occurs and not when an ejaculate would be suitable for breeding or cryopreservation. While scrotal circumference values might need differ for other breeds, the number of sperm is suggested to be useful for all breeds.

Age of Puberty and Impact of Nutrition

Using the criteria described above for puberty, puberty in Holstein bulls has not changed much since 1959 and ranges from 39–47 weeks. In the work of Bratton *et al.* (1959) there was a decrease in age of puberty by 4–7 weeks when the total digestible nutrients (TDN) in a ration were increased from 100% of the suggested daily requirements to 140–160% but bulls maintained on this high level of nutrition eventually decreased in libido. However, in multiple other studies since, there has been no ability to decrease puberty when increasing nutrition relative to a control or medium diet (Flipse and Almquist, 1961; Harstine *et al.*, 2015; Dance *et al.*, 2015). The mean age of puberty in Holstein bulls (Killan and Amann, 1972) was thus identified as 41.1 ± 4.1 weeks of age. The total sperm per ejaculate ($\times 10^9$; mean $\pm$ sem) at puberty was 0.3 ± 0.1 , at 10-weeks post puberty was 3.1 ± 0.4 , at 20-weeks post puberty was 6.2 ± 0.9 and at 30-weeks post puberty at 6.0 ± 1.9 . Holstein bulls should be monitored for puberty at approximately 10 months of age (43 weeks) with the expectation that semen will not be sufficient for normal processing, >70% normal sperm, >60% progressively motile sperm until 1 year of age. If the bull should not yet be producing sufficient normal sperm, then it is likely he will be by an additional 10–12 weeks or by 14 months of age. The reason for the delay in increasing sperm production is that there is a complex interplay between germ cells and Sertoli cells as development proceeds past puberty and it takes time to stabilize with normal cellular signaling. Puberty in well fed Holstein bulls, previously mentioned to be from 39–47 weeks of age and has not changed in the last 50+ years of reports on the subject (Bratton *et al.*, 1959; Killan and Amann, 1972; Amann, 1983).

Puberty in bulls of Jersey and Brown Swiss dairy breeds are similar to Holstein bull while the beef breeds such as Angus and Herford appear to be 1 month later (Senger, 2012). The *B. indicus* breeds are slower maturing with puberty listed as greater than

17 months age (Senger, 2012). We have found that there is quite a range in when *B. indicus* bulls reach puberty, with some bulls not even reaching puberty until after 2 years of age (Siddiqui *et al.*, 2008). This is despite being housed and fed under the same conditions. Selection of bulls which reach puberty earlier is possible and demonstrated that you could select *B. indicus* bulls that reach puberty at an average of 17 ± 2 months of age. The *B. taurus* breeds have already undergone selection and so do not show the same ability for selection and reduction of age of puberty.

Other Effects of Sexual Maturation

To determine if a bull is pubertal, you must collect a semen sample. For artificial insemination (AI), we would generally train a bull to jump a mount animal, usually a steer or bull of appropriate size. The semen would then be collected via an artificial vagina. The young bull should not be asked to mount a bull that is aggressive to that young bull or a negative interaction may impact the ability of that bull to mount and ejaculate in the future. If we simply want a semen sample and the bull would be used for natural breeding of females we would likely use an electroejaculator (Senger, 2012). In either case, the development of the penis is important. As puberty approaches the prepuce of the penis begins to retract from the free end of the penis with the scrotal tissue or the Raphe forming. Many young bulls are housed in groups and the normal activity of young bulls mounting other young bulls resulted in the prepuce retracting as the bull extended his penis and was masturbating. Changes occurring in the artificial insemination industry with the advent of genomic testing to predict genetic value (VanRaden *et al.*, 2009) has resulted in pre-pubertal animals being housed individually and so it may take some time and false mounts for the prepuce to retract from the free end of the penis.

Selection Changes of Bulls Used for Artificial Insemination

The young sire is becoming increasingly important in the AI industry of cattle with the extensive genomic selection of young bulls prior to puberty using whole-genome SNP markers (VanRaden *et al.*, 2009; Aguilar *et al.*, 2010). Where once Holstein bulls in AI centers were 5+ years of age, due to the need for progeny testing, as of 2017 it is rare to see bulls older than 3 and much more common to have bulls <2.5 years of age. As this type of selection becomes more common in beef breeds we are likely to see similar trends and this is already happening with Angus bulls within the US.

At What Age Can Semen be Collected From a Bull?

The theoretical production of sperm from Holstein bulls is depicted vs. age in Fig. 3 as an example for bulls in general. It can be observed that soon after puberty, approx. 10 months of age, sperm production increases yet does not peak until 60 months or 5 years of age. Precise sperm numbers for Holstein bulls can be found in Salisbury *et al.* (1978).

Semen production by the young bull, increases rapidly within 10 to 20 weeks of puberty (Killan and Amann, 1972). The percent motile sperm increased sooner however than the total number of sperm. Although the quality of semen may increase after 1 year of age, it is likely adequate to produce semen for cryopreservation. While the number of AI doses possible will increase with the age of the bull, at 1 year of age it is only 23% of the doses possible at 6–7 years of age. For artificial insemination organizations with bull

Fig. 3 Theoretical sperm output from Holstein bulls. Location now indicated in text following heading “At what age can semen be collected from a bull”; use the minimum of 166 mm width. Adapted from Amann R.P., 1970. Sperm production rates. In: Johnson, A.D., Gomes W.R., VanDemark, N.R. (Eds.), *The Testis* vol. 1. New York, NY: Academic Press, pp. 433–482.

studs, it is clear that the impact of younger bulls being collected is that more bulls are now required to produce the required number of semen doses being sold by each company.

When to Process Semen

The desire to collect semen on younger and younger bulls requires some standards on when to start processing semen. The ejaculates collected on young sires must pass routine quality control standards such as percentage of motile sperm ($>60\%$), percentage of normal sperm ($>70\%$) and the total number of sperm in an ejaculate (>1 billion). The number of sperm in the ejaculate may need to be reduced for sires younger than 14 months of age.

It is suggested that the first ejaculates collected from a bull that is just pubertal be used for disease testing. Semen may then be collected, cryopreserved and used for AI when at least 50 units can be produced at the company standard. Cost of semen processing may be too high per unit when fewer than 50 units will be produced from an ejaculate. With high genomic value bulls, semen should be collected within 5–10 weeks of puberty and may be used for in vitro fertilization if sperm numbers are low. This is particularly important to reduce the generation interval and the selection of bull calves again by genomics. Other bulls may be collected later when the required units of semen can be produced. Within the first 12 weeks following puberty, only 35% of Holstein bull-bulls produce ejaculates suitable for cryopreservation but between 13–24 weeks the acceptable ejaculates increased to 85% and then after to 96%.

There are other potential issues with collecting semen from very young bulls. The presence of a persistent frenulum can be a significant problem. If need be this can be corrected by surgery. Another problem may be genital warts which are a particular problem with group housed bulls. Genital warts are often seen in beef bulls which are commonly group housed prior to or even shortly after puberty. Genital warts can be surgically removed but the bull cannot be used for semen collection until healed. Lastly abrasions or lacerations to the penis may occur in the young or older bullbulls but must be allowed time to recover until routinely ejaculated.

The First Collections on a Bull

The first collections on a bull are critical to get right. There is a substantial difference in size of young bulls and they are also rapidly increasing in size at the time of puberty ([Dance et al., 2015](#)). The changing sizes of the bulls require the proper selection of mounts for semen collection. It is critical the young bull does not have a bad experience and falls off the mount, slips upon mounting or the mount animal is too large. The AI company needs to have mount animals, bulls, steers or a dummy of different sizes to accommodate the changing young bull. It should also be remembered to not false mount the young sire too many times at first. You need to get the young bull familiar with the process and not be intimidated. Turning a young bull out with females also has similar issues. A bull must also learn when a female is in estrus or he could be potentially injured by the female.

Heat Stress Impacts on Spermatogenesis

There are clearly effects of summer heat stress on semen quality and fertility in bulls. In 4 bulls identified as not passing semen quality control during the summer and then collected again in the fall during a cooler season of the year, post thaw motility increased (30 ± 3 vs. 45 ± 6 , $p=0.07$), viability decreased (40 ± 2 vs. 56 ± 3 , $p=0.07$), morphologically normal sperm increased (55 ± 6 vs. 76 ± 1 , $p<0.05$), and ability to fertilize oocytes in vitro increased (65 ± 4 vs. 76 ± 2 , $p<0.05$) ([Parrish et al., 2014](#)). Using a 48 h scrotal insulation model, spermatogenesis in bulls was impacted by this mild heat stress. The heat of scrotal insulation damaged zygotene to pachytene primary spermatocytes, secondary spermatocytes and round spermatids as evaluated by sperm morphology, nuclear shape and ability of sperm to fertilize oocytes in vitro and development of resulting embryos in vitro ([Parrish et al., 2014](#)). The studies suggest that damage to spermatogenesis is likely initiated via damage to the BTB as demonstrated by [Cheng and Mruk \(2012\)](#) to be essential for meiosis. As global climates warm, impacts of heat on bull spermatogenesis will become more pronounced.

Conclusion

Reproduction in the bull involves not only the production of sperm in the testes, but adequate nutrition to assure puberty at a young age, semen collection is maximized and attention to minimizing heat stress.

Glossary

Artificial insemination Assisted reproductive technology used to reproduce livestock animals by using semen from male animal that is collected by artificial stimulation, then diluted and distributed as fresh or frozen insemination doses that are injected in the female reproductive tract by using special catheters, at the time during female reproductive cycle that favors conception.

Boar Adult male pig, domestic or wild, with intact sex organs.

Epididymus Male accessory sex gland that collects and stores sperm cells released from the testis, to convey to them the potential to fertilize an oocyte.

Farrowing Giving of birth by a female pig. Farrowing rate in sows is an indicator of reproductive efficiency and success of artificial insemination or natural mating.

Gilt A young adult or pubertal, virgin female pig.

Intracytoplasmic sperm injection (ICSI) Assisted reproductive technology in animals and infertility treatment in humans that bypasses the natural fertilization process by preselecting and injecting a single sperm cell in a fertilization and development-competent female oocyte, typically followed by in vitro embryo culture and embryo transfer.

Oviductal sperm reservoir Transient sperm storage site within the female Fallopian tube, the oviduct, to which sperm cells bind to await ovulation, the release of female ovum from the ovary in the oviduct.

Sperm capacitation Process by which spermatozoa within the female reproductive tract become competent to seek and fertilize an oocyte, encompassing extensive remodeling of various sperm structures, leading to increased sperm motility and ability of sperm plasma membranes to fuse with oocyte plasma membrane.

Semen sexing Automated process of separation of sperm cells bearing the male Y chromosome from the female X-chromosome-bearing ones, based on lesser DNA content of the former. The goal is to produce offspring of desired sex by artificial insemination.

Sow Adult female pig, domestic or wild, with intact sex organs.

Spermatogenesis Generation of spermatozoa in the testis that starts with multiplication of precursor germ cells by mitosis, followed by two rounds of meiotic division halving the number of chromosomes carried by each resulting daughter cell, and the differentiation of the resultant haploid germ cells, spermatids into spermatozoa with a compacted head and a tail capable of acquiring motility and fertilizing potential.

Transgenic animal An animal carrying a foreign gene (i.e. genetic material from another species) or set of genes inserted in its genome, typically during early embryo development.

Reproductive Organs

The boar has large elliptical testes with thick testicular tunics and adjacent large epididymides, connected to the testis by efferent ducts and to the urethra by the ductus deferens. The tail of the epididymis is dorsally oriented within the scrotum. The boar epididymis is composed of 9 distinct regions, parted into the initial segment, caput, corpus, and cauda epididymis. The scrotum is located in the sub-anal position and divided into two halves by a scrotal raphe. The testis descent occurs shortly before birth. Seminiferous tubules in the boar are very tightly packed, resulting in dense parenchyma from which individual tubules are impossible to extract unless enzymatic digestion is applied. The vesicular gland and bulbourethral glands are very large in the boar, and provide the bulk of seminal plasma volume. Inversely, the prostate is very small. Boars have a long, fibroelastic penis with a sigmoid flexure and a spiraling apex resting within a two-compartment prepuce. Such anatomy, (reviewed in detail by Constantinescu (2017)), facilitates cervical penetration and intracervical semen deposition during mating with a sow.

Spermatogenesis and Epididymal Sperm Maturation

Depending on collection schedule, the daily sperm output of a boar is approx. 15 billion and can bypass 20 billion (up to 120 billion per ejaculate). Sperm concentration can be as high as 200 million/mL, with the total ejaculate volume (both gel-rich and gel-free fraction) approaching 500 mL. As in other species, boar spermatogenesis is divided into proliferative/mitotic and meiotic phase, and a haploid, post-meiotic phase. During the proliferative phase, spermatogonia differentiate into spermatocytes entering meiosis, while a subpopulation of spermatogonial stem cells constantly renews itself to maintain a stable sperm output. The post meiotic phase, during which the haploid spermatids differentiate into spermatozoa capable of acquiring progressive motility and

fertilizing ability, can be divided into distinct steps by which the spermatid nucleus is remodeled and the sperm accessory structures such as the flagellum and acrosome arise. Parameters of boar spermatogenesis may vary between breeds. The duration of spermatogenesis from an undifferentiated A-type spermatogonium to spermatozoon is estimated at 34 days. The staging of seminiferous epithelium, i.e. the identification of the associations of specific germ cell types along the length of seminiferous tubule, points to 8 distinct stages. Spermiogenesis can be divided into 12 steps (Frankenhuis *et al.*, 1982). The length/duration of the cycle of seminiferous epithelium, i.e. the interval between two waves of sperm release from the same segment of a seminiferous tubule, is 8.6 days (Swierstra, 1968). The average duration of each of the 8 stages is 9 days (Franca and Cardoso, 1998). As in other species, boar spermatozoa complete their morphogenesis and undergo final maturation during epididymal transit when they acquire the potential for fertilization and progressive motility. This maturation process is mediated by the modification of existing sperm proteins and adsorption of new ones from epididymal fluid. Clusterin, glutathione peroxidase and lactoferrin are among the major secretory proteins in the boar epididymis (Syntin *et al.*, 1996). The sperm cytoplasmic droplet (CD) slides down the boar sperm tail during sperm transport from the caput to cauda epididymis. Compared to other mammals, a greater proportion of boar spermatozoa retain their distal CD until after ejaculation, at which time factors from seminal plasma are thought to contribute to its removal. Epididymal passage takes approximately 9–10 days and 120–165 billion spermatozoa are stored in a single cauda epididymis. The epididymal reserve could thus be replenished in 3–5 days after depletion.

Sperm Morphology and Abnormalities

The spatula shaped boar sperm head (Fig. 1) is very similar in appearance to bull. The head is approximately 9 μm long and 5 μm wide, and features a prominent acrosomal ridge and a clearly delineated, crescent shaped equatorial segment. The sperm tail (flagellum) measures approximately 30–35 μm , of which ~7–8 μm accounts for the midpiece with mitochondrial sheath. Similar to other mammals, the axonemal 9+2 microtubule arrangement is paralleled by nine outer dense fibers (ODF) along the length of the midpiece, principal piece and end piece, with the fibrous sheath wrapped around the principal piece. The connecting piece linking the sperm tail with the implantation fossa of the sperm head has a typical-for-mammals set of striated columns, directly connected to one ODF each, caging a functional proximal centriole composed of nine microtubule triples. The proximal centriole serves as the organizer of the zygotic centrosome at fertilization, a pattern typical for all mammals except rodents. The distal centriole is dismantled during spermiogenesis, leaving an empty distal centriolar vault (Manandhar *et al.*, 2006).

The most common ejaculated sperm abnormality in boars is cytoplasmic droplet retention (Fig. 2), which is negatively associated with sperm ability to bind to oviductal epithelia and with fertility in AI service (Lovercamp *et al.*, 2007). Other common abnormalities in semen of fertile boars include knobbed or otherwise abnormal acrosomes, and deformed sperm heads, as well as distal cytoplasmic reflex and abaxial attachment of the sperm tail. Nuclear vacuoles and diadems (craters) are less common than in bull spermatozoa. Presumed heritable sperm defects include immotile short tails (not to be confused with stump tail syndrome) and knobbed acrosomes. Examples of genomic influences on boar sperm phenotype and fertility include the of copy number variation in sperm function associated genes (e.g. *WBP2NL* and *ZAN*; (Wang *et al.*, 2015)), and sperm-phenotype affecting polymorphisms in genes such as ubiquitin-ligase *HECW2* (syn. *NEDL2*) associated with the knobbed acrosome defect and an intronic insertion in the *KLP2* gene implicated in flagellar/ciliary biogenesis and function in boars with short immotile tails (Sironen *et al.*, 2010). Conventional analysis of sperm morphology and motility provides useful baseline information on semen quality, but assays of membrane and DNA integrity, mitochondrial membrane potential, viability and sperm molecular makeup are increasingly sought to connect the sperm phenotypes to boar fertility in AI service. Biomarker based sperm/semen analysis and preselection/purification by flow cytometry and other techniques is increasingly used to evaluate boar sperm quality and improve the fertility of AI dose (Sutovsky, 2015).

Seminal Plasma

Seminal plasma (SP) supports ejaculated boar spermatozoa up until their passage through the uterotubal junction. Proposed roles include warding off the immune attack by uterus-infiltrating leucocytes, maintenance of a non-capacitated sperm state and metabolic support of spermatozoa (Rodríguez-Martínez *et al.*, 2009). Seminal plasma components such as micro RNAs and cytokines may stimulate gene expression in the uterus, as a way of priming the uterine lining for conception and implantation (Robertson *et al.*, 2017). Specific to boars, seminal plasma is thought to contain factors facilitating the rejection of CDs by ejaculated spermatozoa. Given the enormous size of vascular and bulbourethral glands, boars can produce as much as 500 mL of semen in one ejaculation, the majority of the volume contributed by SP. Boar SP is rich in inositol, fructose, bicarbonate, magnesium and calcium (Bearden and Fuquay, 2000; Rodríguez-Martínez *et al.*, 2009), and has the highest zinc content among all studied bodily fluids. Spermadhesins, PSP and DQH glycoproteins are the major SP proteins in boars (Jonakova *et al.*, 2007). Adsorbed mainly onto acrosomal surface during ejaculation, spermadhesins have been implicated in sperm-oviduct binding during the formation of the oviductal sperm reservoir. Conversely, spermadhesins such as AQN1 are proteolytically cleaved and shed from the sperm surface during sperm capacitation (Ekhlasi-Hundrieser *et al.*, 2005), to facilitate sperm detachment from the oviductal reservoir in response to ovulation. Such processing of sperm surface proteins may be mediated by intrinsic sperm proteases and possibly by proteolytic and glycolytic enzymes of the oviductal fluid. A high concentration of certain SP proteins is associated with high fertility in AI boars, while other SP proteins may be more abundant in low fertility ones (Flowers *et al.*, 2016).

Fig. 1 Accessory structures of the boar spermatozoon. (A) Acrosome labeled with lectin PNA (green). (B) Equatorial segment, labeled with lectin LCA (green). (C) Postacrosomal sheath labeled with antibody against the WW-domain containing protein WBP2NL (alias PAWP; green). (D) Sperm tail connecting piece, housing the sperm centriole, labeled with antibody against thioredoxin TXL1 (red). (E) Sperm tail midpiece, covered with the mitochondrial sheath, labeled with ProteoStat aggresome detection kit for the labeling of ubiquitinated protein aggregates (red). (F) Sperm tail principal piece covered with fibrous sheath, labeled with antibody against male germline-specific thioredoxing TXND3 (alias SPTRX2; red). (G) Boar round spermatids, with acrosomal caps labeled with lectin PNA (green) and nuclei labeled with antibody against ubiquitin ligase MKRN1 (alias makorin 1, red). (H, I) Porcine oocytes with zona pellucida (red; antibody against ZP3 protein) bound spermatozoa (green acrosomes labeled with lectin PNA). Sperm nuclei were stained with DAPI. Epifluorescence images were superimposed on parfocal transmitted light images acquired using differential interference contrast (DIC) optics.

Mating, Seasonal Effects and Hormonal Control of Gonadal Function

Domestic pigs are not seasonal breeders as the females are cyclic all year. However, boar libido and sperm quality may be influenced by seasonal changes in photoperiod and ambient temperature, particularly summer heat stress (Ross *et al.*, 2017). Given the duration of spermatogenic cycle and epididymal passage, some such adverse effects can last for weeks/months after the exposure, and can be mimicked by scrotal insulation. In addition to reduced sperm quality, sperm content of proteins associated with aberrant sperm phenotypes, such as ubiquitin, increases after heat stress (Lovercamp *et al.*, 2007). Compared to other mammals,

Fig. 2 Scanning (A, B) and transmission (C–E) electron micrographs of boar spermatozoa on the surface of oocyte zona pellucida (A, B, D; note the vesiculation of the acrosome in panel D, caused by zona-induced acrosomal exocytosis), in the epididymis (C; note prominent cytoplasmic droplets – arrows), and at the time of sperm incorporation in the oocyte cytoplasm (E; sperm tail is still outside of the oocyte, which was fertilized zona-free *in vitro*, in this case). Photo credit, panels (A) and (B), Shawn Zimmerman, PhD.

boars produce as much as 500 mL of ejaculate, mainly due to the large volume contribution by accessory sex gland secretions (Constantinescu, 2017). Boars are uterine semen depositors, meaning that their glans penis reaches and partially penetrates the cervix during mating. Ejaculation occurs in fractions (segmented ejaculation) over a period of time as long as 10 min (Bearden and Fuquay, 2000). The initial portion of the sperm-rich fraction appears to have the highest content of epididymal fluid proteins, while seminal plasma/fluid proteins produced by accessory sex glands prevail in the main volume of sperm-rich fraction (Rodríguez-Martínez *et al.*, 2009).

Boar libido and testicular function is guided by the hypothalamic-pituitary-gonadal axis. Hypothalamic gonadotropin releasing hormone (GNRH) stimulates pulsatile secretion of follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary, which in turn stimulates steroidogenesis and testosterone production by testicular interstitial Leydig cells (Lents *et al.*, 2017). Epididymal sperm maturation and epididymis sustenance is stimulated by lumicrine factors from rete testis fluid- accompanying spermatozoa as they travel through the efferent ducts to the caput epididymis. Puberty starts generally at around 120–180 days of age but as early as 56–84 days in Meishan boars. Between the two mammalian isoforms of gonadotropin releasing hormone, GNRH2 and its receptor seems to control testosterone production in boar, with a feedback loop regulated by RF-amide-related peptide 3, which appears to control both the testis and hypophysis, and suppresses GNRH-I secretion from the hypothalamus (Lents *et al.*, 2017). Within the seminiferous tubule, spermatogonial renewal, proliferation and differentiation are regulated by an intricate signaling network, involving growth factors, cell cycle regulators and transcription factors.

Sperm Transport and Capacitation

After uterine deposition, boar spermatozoa migrate to the oviduct within 1–2 h after mating as they reach the site of oviductal sperm reservoir in the distal part of the oviductal isthmus, where they await ovulation (Suarez and Pacey, 2006). Detachment from the reservoir upon capacitation and hyperactivation is mediated by proteolysis causing the shedding of spermadhesins from the sperm

head acrosomal surface (Ekhlesi-Hundrieser *et al.*, 2005), mirroring the cleavage and release of the BSP proteins from capacitating bull spermatozoa. Capacitation causes a series of signaling, biochemical and structural remodeling events that release spermatozoa from oviductal reservoir site, remodel the sperm surface, endow spermatozoa with hyperactivated motility and prepare them for interactions with the oocyte at fertilization. Hallmarks of boar sperm capacitation common with sperm capacitation in other mammals include tyrosine phosphorylation, Ca-influx and cholesterol removal (Gadella, 2017), as well as recently postulated regulation by the 26S proteasome (Kerns *et al.*, 2016). Capacitation is not fully reversible, and spermatozoa that fail to reach the oocyte after detaching from oviductal sperm reservoir die within 4–6 h (Suarez and Pacey, 2006). Consequently, premature sperm capacitation in the semen processed for AI reduces AI dose fertility.

Fertilization and Zygotic Development

The nature of oocyte produced sperm attractant, if any exists in pigs, is not known, though progesterone is currently favored for a role in mammalian sperm-oocyte chemotaxis. Of the three porcine zona pellucida (ZP) composing proteins (ZPA/ PZP1 - homologue of mouse ZP2; ZPB/PZP3 α , homologue of human ZP4; ZPC/PZP3 β , homologue of mouse ZP3), the ZPB-ZPC complex rather than a single ZP protein species is thought to act as receptor for sperm-ZP adhesion (Yonezawa *et al.*, 1997). Both conventional proteases and acrosomal proteasomes (Zimmerman *et al.*, 2011) have been implicated in ZP digestion and penetration by boar spermatozoa. After sperm passage through the ZP, oocyte JUNO and sperm IZUMO1 proteins are the likely surface ligands involved in sperm adhesion to the oocyte plasma membrane, the oolemma (Tanihara *et al.*, 2014). The nature of fusogenic molecules involved in the gamete plasma membrane fusion after initial adhesion is not known. An alternative model proposing a phagocytosis-like mechanism of sperm incorporation in the oocyte has been proposed in mammalian fertilization. Porcine gametes initially fuse at the sperm head equatorial segment and the postacrosomal perinuclear theca solubilizes quickly in the ooplasm, releasing sperm-borne oocyte activating factors (SOAF). The currently favorite SOAF molecule, phospholipase PLCZ1 is present in boar spermatozoa but its localization and solubility during fertilization do not support a role in oocyte activation, prompting research into alternative SOAF candidates such as PAWP/WBP2NL (Oko *et al.*, 2017). Following sperm incorporation in the ooplasm, which involves cortical microfilament cytoskeleton of the oocyte (sperm tail beating stops at gamete fusion), the sperm nucleus decondenses quickly, and both maternal and paternal pronuclei (PN) form in synchrony, with the paternal PN being larger than the maternal one. The sperm mitochondrial sheath, which remains associated with paternal PN early after fertilization, is degraded very quickly, i.e. before first embryo cleavage, to promote post-fertilization sperm mitophagy as way of enforcing maternal inheritance of mitochondria and mtDNA, and thus preventing heteroplasmy (coexistence of paternal and maternal mitochondrial genomes in the same individual; (Song *et al.*, 2016)). With such a mechanism being specific to gametes, somatic cell mitochondria are not recognized as foreign, causing some piglets born from embryos reconstructed by somatic cell nuclear transfer (SCNT) to be heteroplasmic.

In Vitro Fertilization (IVF) and Intracytoplasmic Sperm Injection (ICSI)

While the first live birth after surgical transfer of flushed porcine embryos reportedly occurred in 1950, IVF embryos by surgical (with frozen spermatozoa) or non-surgical transfer were produced more recently. Porcine oocytes mature in vitro in the presence of gonadotropins for 44 h, typically with a medium change at 24 h; thus, IVF is a three day cycle. Cumulus cells are removed prior to IVF. Typical sperm concentration is 0.5–1 million/mL of IVF medium based on a modified tris-buffer (Abeydeera and Day, 1997). In vitro capacitation prior to sperm mixing with oocytes is not required as the spermatozoa capacitate in IVF medium. Spermatozoa incorporated into oocyte cytoplasm are first observed at 5–8 h after gamete mixing. Polyspermy is common in vitro (but not prevalent in vivo) due to reduced quality/developmental potential of in vitro matured oocytes and lack of oocyte exposure to oviductal secretions. Polyspermy can be mitigated by IVF culture medium supplementation with isolated oviductal fluid or its components such as osteopontin, or with recombinant deubiquitinating enzymes. Common protocols call for transfer from fertilization medium to a development promoting embryo culture medium at 6 h after sperm-oocyte mixing. First embryo cleavage typically occurs within 24 h after gamete mixing. Compacting morulae appear on day 5 and hatching blastocysts on Day 7. Zona free oocytes can also be fertilized in vitro and the resultant embryos used to produce piglets by embryo transfer.

Apart from sperm vectored transgenic ICSI, porcine ICSI is performed for research rather than for clinical or production purposes. Contrary to humans and non-human primates, and similar to murid and bovine ICSI, boar spermatozoa disassemble poorly when injected in porcine oocytes, warranting the use of a piezo-driven injector. Sperm disassembly and pronuclear development can be improved by supplementation of culture media with cysteine, with which live births have been achieved (Katayama *et al.*, 2007).

Artificial Insemination (AI)

Semen is most commonly collected from phantom-trained boars by the gloved hand technique or automated collection devices (pneumatic or physically applied pressure), in fractions (Bearden and Fuquay, 2000). Only the sperm-rich second fraction is typically processed for AI out of concern for low sperm concentration and high bacterial count in the initial sperm fraction (first 10 mL); which, however, appears to be most resistant to cryodamage and most capable of reaching the oviductal sperm reservoir

after AI (Rodriguez-Martinez *et al.*, 2009). Commonly desired minimal sperm progressive motility is 80%, with total sperm count of at least 60 billion, concentration of 100–200 million/mL (sperm rich fraction) and 80–90% normal morphology by conventional light microscopic assessment; although the rejection limits for an ejaculate may vary by boar stud. Depending on deposition site, a single AI dose contains 1–3 billion spermatozoa suspended in 80 mL of extended semen (Bearden and Fuquay, 2000). Boar semen freezes poorly, and spermatozoa may capacitate prematurely (Yeste *et al.*, 2017). Semen pooling is a common practice in the US because of a high degree of variation in semen quality between boars and within a boar between collections. Single sire AI is desired by the swine industry, which may need high precision management of boar reproductive function. Increasing use of post-cervical and deep intrauterine insemination, semen freezing and lower sperm doses (Yeste *et al.*, 2017) drive the development of novel AI catheters. Sperm quality and fertility in boars is influenced by genetics, nutrition, housing, seasonal weather and photoperiod effects, and disease, and further impacted by semen handling and processing. Semen sexing is possible in boars and live births have been achieved, but sexing is not (yet) practical and thus in limited use due to large semen volume, high sperm number needed per AI dose and poor freezability. Progress is being made as the AI technology improves and tubal insemination becomes more common. Improvements of AI dose have been achieved by various purification techniques and by supplementation of boar semen extenders with antioxidants [reviewed by Sutovsky (2015)].

Transgenic Boar as a Biomedical and Biotechnological Animal Model

As a biomedical model, domestic pig is a valuable alternative to rodents because of a manageable generational interval (114 day gestation) and large litter size, and particularly because the size and anatomy of pig organs is similar to humans, favoring the pig as a model for testing surgical procedures, as well as for xenotransplantation. Furthermore, in some cases transgenic pigs bearing mutations mimicking human genetic disease are more likely to have human-like disease phenotypes and symptoms than transgenic rodents (Prather *et al.*, 2013). Importantly, domestic pigs are now routinely genetically modified. Boar-relevant transgenic pig models include green-fluorescent proteasome pig for the study of sperm function, cystic fibrosis transmembrane receptor (CFTR) mutant pig with congenital absence of vas deferens, the NANOS2 male germline ablated pig and the porcine reproductive and respiratory (PRRS) virus resistant pig which is relevant to boar fertility because the PRRS virus is transferred by semen during AI. Because of a lack of chimera-suitable porcine embryonic stem cells, the most common method for the production of transgenic pigs is by somatic cell nuclear transfer (SCNT) of genetically modified fibroblasts, and more recently by zygotic CRISPR/CAS microinjection. Earlier successes have been achieved, among other approaches, by direct zygotic-pronuclear injection of DNA constructs, and by sperm-vectored IVF and ICSI transgenesis.

Anatomy of the Equine Male Reproductive Tract

In the stallion, the paired testicles are located in the inguinal region and covered by the scrotum. The scrotal skin is hairless or finely haired, often pigmented and contains numerous sweat glands. The testicles are in a horizontal position and have the shape of plump eggs with their size varying between a hen's egg and a man's fist depending on size and age of the stallion. The epididymal body (*corpus epididymidis*) is lying dorsally on the respective testis, its head (*caput epididymidis*) is covering the cranial testicular pole, and its tail (*cauda epididymidis*) is located at the caudal testicular pole. While the head is closely associated with the testis, the epididymal tail is clearly protruding and therefore easily accessible by manual palpation (Fig. 1). A fibrous structure, the proper ligament of the testis, attaches the epididymal tail to the testis. The efferent ducts of the testis terminate into the epididymal head and merge to form the epididymal duct. The deferent duct is a direct continuation of the epididymal duct. It ascends from the epididymis into the spermatic cord and enters the abdominal cavity through the inguinal canal. It finally opens into the proximal part of the urethra at the *colliculus seminalis* (seminal hillock). The terminal part of the duct is enlarged and forms the ampulla of the deferent duct, one of the accessory sex glands. The deferent duct is joined by the excretory duct of the respective vesicular gland; the shared termination of them is also called the ejaculatory duct. In horses, only the compact part of the prostate gland exists and consists of two lateral lobes and an isthmus (prostatic body) traversing the urethra. Multiple excretory ducts of the prostate terminate into the urethra in close proximity to the ejaculatory ducts. The paired bulbourethral glands are located near the pelvic outlet and are covered by the respective bulboglandular muscle. Several secretory ducts terminate dorsally into the urethra. The penis of the horse is of the musculocavernous type. The opening of the prepuce is located directly behind the umbilicus. The shape of the equine glans penis is similar to that of a mushroom, the *corona glandis* being its widest part. The urethra protrudes into a distinctive central fossa (*fossa glandis*) at the free end of the corona (Fig. 2). The pronounced increase in size of the penile glans at maximal erection allows for dilatation of the mare's cervical canal at copulation resulting in deposition of the ejaculate directly into the uterine lumen in this species.

Reproductive Activity and Behaviour in Stallions

Horses are seasonal breeders with sexual activity occurring in spring and summer. The increase in sexual activity is stimulated by increasing day length after the winter solstice. However, in domesticated horses, breeding selection has diminished seasonal reproductive activity because conception early in the year is considered advantageous to horse breeds participating in races or equestrian competitions early in life. While in less domesticated horse breeds, the ovulatory season is limited to the time period between

Fig. 1 Photograph depicting right testis and epididymis collected at surgery of a mature healthy stallion. (A) testis, (B) caput epididymidis, (C) corpus epididymidis, (D) cauda epididymidis, and (E) spermatic cord. Reproduced from Aurich, C., Vetmeduni Vienna, Austria.

May and October, in more domesticated breeds like Thoroughbreds or riding-type horses a certain percentage of females continues cyclic ovarian activity throughout winter. In contrast, stallions are fertile throughout the year irrespective of breed, although testicular size and function as well as sexual behaviour are reduced outside the breeding season (**Fig. 3**). Testicular weight, parenchymal weight and seminiferous tubular volume increase by 30% from the beginning to the height of the breeding season. Due to increased activity of the accessory sex glands during the breeding season, also changes in ejaculate characteristics such as increased volume but decreased sperm concentration occur. In addition to photoperiod, exogenous factors such as age, reproductive state, nutrition, body condition and environmental temperature contribute to changes in reproductive activity of the horse (reviewed in [Aurich \(2016\)](#)).

In the normal male horse, testicular descend into the scrotum occurs between 30 days before and 10 days after birth. Puberty occurs at an age of 56–97 weeks with an average of 83 weeks ([Naden et al., 1990](#)). In stallions below three years of age, semen quality may be poor and male horses do not achieve maximal efficiency in spermatogenesis before an age of 5–6 years when semen production and fertility reach a plateau phase. From an age of 14 years onwards, semen quality may decline due to age-related testicular degeneration and impaired epididymal function. This may finally result in azoospermia and infertility in old stallions while characteristic male sexual behaviour is often maintained ([Amann, 2011](#)).

Under feral conditions, horses live in stable family groups that typically consist of adult mares, their young offspring and one to five adult harem stallions. Strong social bonds among stallions and mares exist resulting in continuous interaction among members of the harem. Under today's breeding conditions, the situation is completely different: the contact time of an individual stallion to mares is often minimal. If mating by natural cover takes place, reproductive receptivity of the mares is mostly not tested by the sire selected for breeding but instead the mare's sexual behaviour will be determined by exposing her to a less valuable stallion ("teasing"). The contact of stallions to oestrous mares is therefore often limited to the mating procedure itself. If they are used for artificial insemination, the time of contact to mares may be even more limited. The stallion is often only exposed to an oestrous mare for stimulation of sexual arousal when brought to the semen collection room. In well-trained stallions, semen collection may even take place on a breeding dummy in complete absence of a mare. It has been suggested that this man-made breeding routine contributes to dysfunctions of sexual behaviour and subfertility among hand-bred domestic horses when compared to equines breeding at liberty ([McDonnell, 2000](#)). The social environment of breeding stallions may impair ejaculate characteristics and contribute to increased cortisol concentration. Although fertility of horses kept under the described management may be lower than in their feral conspecifics, it is still considered acceptable and results in end of season pregnancy rates of 80% and foaling rates of 70%. However, unlike other domestic animal species, stallions are mainly selected for breeding based on their phenotypic

Fig. 3 Time (min; mean+SEM) from entering the breeding barn until ejaculation in Shetland stallions ($n=7$) kept under ambient photoperiod in different months of the year. Reproduced from Aurich, C., Vetmeduni Vienna, Austria.

characteristics and athletic performance, but not on reproductive performance. The current knowledge on genetic traits involved in fertility in the horse is still limited, but some candidate genes contributing to infertility in stallions have already been identified (Giesecke *et al.*, 2010).

If a stallion has the opportunity to breed mares at liberty, i.e., under conditions similar to the feral, an oestrous mare will usually start showing increased interest in the male in response to his sexual attractiveness. Presentation of characteristic oestrous behaviour of the mare (posture with lowered pelvis and straddled hind limbs accompanied by deviation of the tail, exposition of the perineal region and “clitoral winking”, i.e., rhythmic eversion of the clitoris, as well as frequent voidance of small quantities of urine) will stimulate sexual arousal in the stallion. This is mostly accompanied by an olfactory response of the male including frequent flehmen (curling of the upper lip for presentation of the vomeronasal organ for better perception of the mare’s odour, Fig. 4). It has been assumed that frequent urination of the oestrous mare induces chemosensory priming of the stallion for reproduction (Crowell-Davis, 2007). Erection is followed by mounting and insertion of the penis into the mare’s vagina. Some vigorous pelvic thrusts of the stallion will finally lead to ejaculation. In the horse this is characterized by deposition of five to eight jets of seminal fluid. Ejaculation starts with deposition of spermatozoa-free presperm fluid that originates from the bulbourethral glands. This is followed by the sperm-rich fraction and eventually a sperm-poor gelatinous fraction with its major component coming from the seminal vesicles (Kosniak, 1975). Presence and volume of the gelatinous fraction depends on season and sexual arousal with higher volumes during the breeding season and after prolonged stimulation of sexual behaviour.

Endocrine Regulation of Stallion Reproduction

In the horse, both endogenous and environmental factors affect the synthesis and secretion of GnRH from the hypothalamus via higher brain areas. These include factors like the day-night ratio, temperature, food range and composition, energy intake, social status of the animal and others. Hypothalamic activity is also modulated by endogenous steroid feedback mechanisms. In the stallion, testosterone activates endogenous opioidergic systems inhibiting GnRH release and thus limiting synthesis and release of testicular steroid hormones. Opioidergic activity is further modulated by season with highest opioidergic tone being present outside the breeding season (Aurich *et al.*, 1994). Reduced GnRH release is assumed to be the key to inhibition of reproductive function in stallions outside the breeding season. This depends on the prolonged presence of melatonin associated with long nights and short days during the non-breeding season in winter. During this time, LH and testosterone release are reduced. Besides seasonal changes in reproductive activity, not only in wild horses such as the Przewalski horse but also in domesticated horses, metabolism is reduced. This has been interpreted as the capacity of equines for seasonal adaptation to environmental conditions with the aim to limit energy expenditure. Such mechanisms have been suggested to further influence reproductive functions in horses.

Fig. 4 Flehmen of a warmblood stallion when exposed to an oestrous mare for stimulation before semen collection. Reproduced from Aurich, C., Vetmeduni Vienna, Austria.

In the stallion, the mean GnRH pulse interval is approximately 30 min. A high synchrony between GnRH, LH and FSH pulses in pituitary effluent blood has been demonstrated (Irvine and Alexander, 1988). A differential release of LH and FSH at least in part may be caused by inhibin which is produced by the Sertoli cells and exerts a negative feedback on FSH secretion also in the stallion.

In prepubertal male horses, FSH and LH concentrations in plasma peak at about 40 weeks of age, decline thereafter and rise again at puberty. The rise at 40 weeks is not associated with increased testosterone concentration which will not increase before the onset of puberty. Before and during puberty, FSH is assumed to be critical for Sertoli cell development and proliferation, while after puberty it induces the release of paracrine Sertoli cell factors involved in regulation of spermatogenesis. LH regulates the synthesis and secretion of testicular steroid hormones from Leydig cells (reviewed by Roser (2008)). However, in the prepubertal stallion, LH receptors are also present in seminiferous tubules suggesting an involvement of LH in their development. In the equine testis, besides testosterone also oestrogens are produced and secreted in considerable amounts. While in prepubertal stallions, immunoreaction for aromatase, a key enzyme for oestradiol-17 β synthesis, was observed within both Leydig cells and seminiferous tubules, in adult stallions, aromatase was restricted to Leydig cells (Herrera-Luna *et al.*, 2016). In immature stallions, sexual steroid concentrations remain at baseline until puberty when the ratio of testicular testosterone to oestrogen changes due to a variation of Leydig cell responsiveness to LH (Roser, 2008). In adult stallions, oestrogen concentrations in the peripheral blood are considerably higher than in mares irrespective of reproductive state. The expression of aromatase (CYP19A1), in testicular tissue increases with stallion age (Herrera-Luna *et al.*, 2016). During the breeding season, oestrogen concentration in the blood circulation is higher than outside the breeding season. These findings highlight the importance of oestrogens for the maintenance of testicular function in stallions. High concentrations of steroid hormones around seminiferous tubules have been suggested to be essential for maintenance of spermatogenesis also in the horse. However, concentrations of steroid hormones in peripheral blood of stallions vary considerably and are not stable, but episodic elevations occur. Concentrations of steroid hormones determined in the testicular vein are up to 100fold higher than in jugular venous blood. Stimulation of testosterone release by injection of the LH analogue hCG is suggested a better tool for assessment of Leydig cell function than determination of testosterone in a single blood sample. In stallions with physiologic testicular function, administration of hCG results in an immediate rise of peripheral testosterone concentration with peak values being reached within 120–180 min. A second increase in testosterone concentration occurs 72–96 h after hCG as a result of increased steroid hormone synthesis. In contrast to other species, male behaviour in stallions is not directly related to peripheral testosterone and/or oestrogen concentration.

Recently, Anti-Müllerian Hormone (AMH) has gained some interest as a potential biomarker for the presence and function of testicular tissue in horses. AMH is produced by Sertoli cells from the initiation of testicular differentiation, i.e., already in the fetus. The production continues after birth and AMH concentrations are high in the plasma of prepubertal male horses but decrease after puberty. In mature stallions with physiologic reproductive functions, AMH concentration is increased during the breeding season as a cause of stimulated Sertoli cell function. AMH concentrations are elevated in cryptorchid stallions in comparison with intact stallions or geldings (Claes *et al.*, 2013).

Among paracrine factors suggested to be involved in the regulation of testicular function, prolactin and growth hormone (GH) have been addressed in more detail in the stallion. In the horse, prolactin concentration in blood significantly changes with season and is maximal during the breeding season. An involvement of prolactin in testicular recrudescence in spring has been suggested. In male golden hamsters, prolactin stimulates LH receptor expression on Leydig cells but such interactions could not be confirmed in the male horse. In humans, GH deficiency is associated with fertility problems. No seasonal changes in GH secretion in stallions were demonstrated. Treatment of healthy fertile stallions with the somatostatin analogue octreotide transiently decreased their semen motility and also reduced an hCG-induced testosterone release. An involvement of GH in testicular and/or epididymal function in stallions was therefore suggested (reviewed by Roser (2008)).

Spermatogenesis and Semen Characteristics in the Stallion

Complete spermatogenesis in the male horse requires approximately 57 days. It can be further divided into spermatocytogenesis (19.4 days), meiosis (19.4 days) and spermiogenesis (18.6 days). Transport through the epididymis takes another 9–14 days. Sperm morphology therefore reflects events that occurred in the past two months. In general, the structure of the equine spermatozoon is similar to that of other species. It has a length of approximately 60 μ m. The head is oval elongated, the anterior third being its widest part. From the side, the equine sperm head is relatively flat. Altogether, the sperm head resembles the shape of a spatula. The anterior two-thirds are overlaid by the acrosome. Significant stallion effects on sperm head dimensions have been reported, ranging from somewhat thinner and elongated to shorter and broader. The impact of these variations on fertility is unclear but a tendency of larger heads in subfertile stallions has been suggested (Casey *et al.*, 1995; Brito, 2007).

The efficiency of spermatozoal production is defined as the number of spermatozoa produced per day and gram of testicular parenchyma. In the stallion, this characteristic is affected by season, is maximal during the breeding season and assumed to be similar among individuals with physiologic fertility. In stallions, efficiency of spermatozoal production has been determined to average 19 million spermatozoa per day and gram testicular parenchyma. In consequence, the total daily spermatozoal production (DSP) of a given stallion depends on the size of his testes and varies considerably among stallions. Testicular size and DSP gradually increase from puberty onwards until approximately an age of 6 years. DSP has therefore not reached its maximum when most stallions start their breeding career at an age of 2 or 3 years (reviewed by Amann (2011)). In the stallion, spermatozoa are produced continuously from puberty onwards. Considerable degeneration of germinal cells occurs already during the breeding season but is increased during the non-breeding season. This is associated with a reduced number of germinal cells per Sertoli cell and reduced

daily sperm production outside the breeding season. Modulations in daily sperm output with regard to season also depend on breed and may be pronounced in less domesticated breeds like Shetland ponies (Fig. 5). While in seasonal anovulatory mares, the onset of ovulatory cycles in spring can be advanced approximately 60 days by exposure to a long-day light program (16 h light – 8 h darkness) from the beginning of December (northern hemisphere), such a light program was not effective in increasing sperm output in stallions early in the breeding season. Only a more complex light program (6 months of short days starting in July followed by 4 months of long days) was able to influence testicular function and daily sperm output in stallions (reviewed by Aurich (2016)).

Thermoregulation within the scrotum is of importance for maintenance of spermatogenesis which will be completely arrested in abdominal testes such as in cryptorchids due to the temperature within the abdomen. Increased temperature may also impair epididymal function and result in declining semen quality (increased number of detached sperm heads) within a few days. Within the scrotum, temperature is kept approximately 3–5°C below body temperature because of evaporation of moisture from the scrotal skin, counter current heat exchange within the *plexus pampiniformis* and changes in the position of the testes relative to the abdominal wall due to relaxation respective contraction of the *musculus cremaster* and *tunica dartos* muscle.

After having left the testes via the ductuli efferentes, spermatozoa are still infertile and achieve progressive motility and fertility only during passage transport through several sections of the epididymal tract. These have not yet been characterized in detail in the stallion. During sperm transport through the epididymal tract, fluids and other material of testicular origin are replaced by epididymal secretions. Function of the epididymal epithelium depends on the presence of testosterone and the detection of aromatase in the equine epididymis suggests that it is further converted into oestradiol-17 β in this location (Herrera-Luna *et al.*, 2016). In the stallion, the process of spermatozoal maturation takes place in the caput and corpus epididymidis and spermatozoa recovered from the cauda epididymidis after surgical castration have been successfully used for the insemination of mares. However, these spermatozoa do not start moving before being mixed with accessory sex gland fluids or appropriate buffer solutions. The epididymal tail together with the deferent duct and its ampulla is therefore assumed to be a major storage area for spermatozoa in the stallion. Movement of spermatozoa through the epididymal tract of the caput and corpus epididymidis depends on continuous peristaltic contractions of its smooth muscular wall and is not hastened by ejaculation. It requires approximately 4.1 days in a stallion. In contrast, the smooth muscular wall of the cauda epididymidis is usually inactive and the time spermatozoa spend in this part of the epididymal tract is influenced by ejaculation and ranges from 2 to 3 days in a sexually active stallion to 10 days in a sexually rested stallion. Depletion of the epididymal sperm reservoir can be achieved if semen collection is performed daily on at least 5 consecutive days, i.e. the total sperm number of the ejaculate collected on the last day is normally reflecting the daily sperm output of the testes in an individual stallion. However, in a sexually rested healthy stallion, accumulation of overaged spermatozoa in the cauda epididymidis does not occur. It has been assumed from other species that spermatozoa will pass from the deferent duct into the pelvic urethra and will be voided at urination resulting in a continuous discharge of spermatozoa from the epididymal reservoir (Amann, 2011). Masturbation in stallions occurs on a regular basis independent of sexual activity but will only rarely result in complete ejaculation and therefore not contribute to considerable spermatozoal loss (McDonnell, 2000).

The use of cooled-shipped semen has become a routine method in the equine breeding industry since the 1980s (Aurich, 2012). Equine semen stored at 5°C for about 24 h maintains fertility similar to that of fresh semen. When stored for longer time periods, motility, velocity and fertilization rates of equine sperm decline markedly but with considerable variation among stallions. Loss of motility and fertilizing ability has been mainly attributed to lipid peroxidation processes within the sperm plasma membrane. The two main metabolic pathways of energy production by spermatozoa are glycolysis and oxidative phosphorylation. Spermatozoa from most species appear to depend mainly on glycolysis for ATP production; however, the significance of glycolysis for equine spermatozoa is not yet completely clear. It has been recently shown that equine spermatozoa depend at least in part on oxidative phosphorylation to meet their energy requirements. It has therefore been suggested that rapidly metabolising spermatozoa and not

Fig. 5 Total sperm count (10⁹; mean+SEM) of ejaculates collected from Shetland pony stallions (n=8) kept under ambient photoperiod in different months of the breeding season. Reproduced from Aurich, C., Vetmeduni Vienna, Austria.

nonviable or dying sperm are responsible for the generation of reactive oxygen species in equine semen (Varner *et al.*, 2015). In addition to cooled-stored semen, also cryopreserved semen is gaining increasing interest in the horse industry despite the fact that post-thaw semen quality and fertilization rates are still lower than with fresh and cooled-stored semen. The variability in semen viability and pregnancy rates among stallions, breeds and even among ejaculates of a given stallion is large. The phospholipid profile of the equine sperm plasma membrane which is similar to that of the boar contains high levels of docosapentaenoic acid (DPA), an omega-6 polyunsaturated fatty acid (PUFA), and docosahexaenoic acid (DHA) an omega-3-PUFA. DPA content varies among stallions, is influenced by season and has been suggested the main reason for differences in sperm cryosurvival.

Semen analysis provides important information and allows to assess fertility problems or to develop strategies for optimizing fertility in an individual stallion. However, correlations between semen characteristics and fertility may be low. This is also due to the fact that the repeatability of semen characteristics among ejaculates within an individual stallion is only low to moderate. Factors such as season, time of sexual rest, state of sexual arousal, semen collection technique and other contribute to this variation. Fertility is further influenced by semen handling and processing procedures during and following semen collection, management of stallion and mares as well as the number of mares bred per stallion. Semen is routinely collected with an artificial vagina on either an oestrous mare or on a dummy (Fig. 6) in the presence of a mare. The time and number of mounts until successful semen collection is influenced by libido of the stallion as well as semen collection practice. Stallion and personnel have to be well trained and the equipment has to be adjusted to the individual stallion to provide optimal conditions. Repeated mounts until successful ejaculation do not only affect semen characteristics but also increase the probability that semen is contaminated with bacteria from the stallion's genital surface which may impair semen quality especially if semen is further processed for use in artificial insemination. Parameters that are included into routine semen analysis in stallions are semen volume (total volume, gel-free semen volume, gel-volume), sperm concentration ($10^6/\text{mL}$), total sperm count (10^9 ; gel-free volume $\times$ sperm concentration), sperm motility as well as the percentage of morphologically normal sperm. Mean values for these semen characteristics are given in Table 1. Semen volume is highly influenced by breed, size, age, season, state of sexual stimulation as well as collection technique. It may thus vary from a few to several hundred milliliters. Sexual arousal or repeated unsuccessful attempts of semen collection will increase the volume considerably due to increased contributions of the accessory sex glands. Semen volume is therefore negatively correlated with sperm concentration which in healthy normal stallions varies between approximately 100 and 300×10^6 spermatozoa mL^{-1} or even more. For semen processing with the aim to produce cooled-stored or cryopreserved semen, higher sperm concentration is advantageous. Total sperm count is highly correlated to testicular size and varies according to breed, size and age of the stallion. Sperm motility is historically an important characteristic in stallion semen analysis even if the impact on fertility is often questioned. Sperm motility in a stallion with good fertility will in most cases exceed 70% with the majority of sperm being progressively motile. Due to abaxial attachment of the sperm mid-piece to its head, most equine spermatozoa produce a circular motion of varying radius. If performing motility analysis, well-controlled conditions are inevitable. With the increasing impact of artificial insemination in the equine industry, computer assisted semen analysis is more and more used also with stallion semen. Sperm morphology is a parameter which reflects either disturbances in spermatogenesis, epididymal sperm maturation and storage or during semen collection and processing. In raw equine semen of acceptable quality, the percentage of spermatozoa with pathological morphology should not exceed 30% and increased percentages may reflect impaired fertility (Brito, 2007; Amann, 2011; Varner *et al.*, 2015).

Table 1 Mean values and standard deviations of semen characteristics from 47 stallions (age 2–26 years) belonging to 7 different breeds

	Mean	Standard deviation
Total volume (mL)	63.6	45.9
Gel-free volume (mL)	45.3	30.9
Gel volume (mL)	16.8	24.7
Sperm concentration ($\times 10^6/\text{mL}$)	178.0	168.0
Total sperm count ($\times 10^9$)	7.3	6.9
Total motility (%)	72	16
Morphologic aberrations of spermatozoa		
Abnormal sperm heads (%)	7.1	5.9
Proximal plasma droplets (%)	13.1	10.3
Distal plasma droplets (%)	8.1	11.7
Abnormal tails (%)	10.9	9.2
Detached heads (%)	2.6	4.8

Reproductive Organs of the Ram

In comparison with males of most species the testes of rams (**Fig. 1**) are large (each testis is approximately 0.5% of body weight) and highly productive. For example, they are 25 times as large relative to body weight as human testes. The paired testis are situated outside of the body in the scrotum and contain networks of tubules, termed seminiferous tubules, in which spermatozoa are formed from progenitor stem cells called spermatogonia. Testicle size, as measured by the scrotal circumference (width of the paired testicles at the widest point), is positively correlated with sperm production (Ley *et al.*, 1990; Soderquist and Hulten, 2006). Interestingly, rams with larger testicles sire more prolific ewes suggesting a genetic component to fertility spanning both genders (Goelz, 1999). Sperm exit the seminiferous tubules through the rete testes and the efferent ducts before entering the epididymis. The epididymis is single highly coiled tube on the outer surface of each testicle where sperm finish maturing and then are stored for later ejaculation. The epididymis is composed of a caput (head), corpus (body) and cauda (tail), and is attached to the testicle on the cranial pole and wraps around it to the caudal pole of the testis. It can be visualized and easily felt by palpation as a large lump under each testis. A large firm tail to the epididymis indicates that the ram has good reserves of sperm (Schoenian, 2016). Sperm then move from the cauda epididymis to the ductus deferens (vas deferens). During sexual excitement, contractions of the cauda epididymis and ductus deferens move sperm to the point where both ducts converge at the pelvic urethra in an area termed the colliculus seminalis. The final section of the ductus deferens is enlarged and glandular and is termed the ampulla. As the sperm enter the colliculus seminalis they are combined with seminal plasma contributed by the ampullae of each ductus, a set of paired seminal vesicles that are large and distinct, the prostate gland and the bulbourethral gland (cowpers gland). The sperm and the seminal plasma together are termed semen. At ejaculation, strong contractions of the urethralis muscle surrounding the pelvic urethra and contractions of the ischiocavernosus and bulbospongiosus muscles force the semen through the penile urethra and out through the urethral process (filiform appendage), which spins rapidly and sprays the ejaculate on the external os (opening) of the cervix. The bulk of the ejaculate, which is approximately 3–5 mL, is deposited at the external cervical os in the anterior vagina. The ram has a fibroelastic penis which is retracted into the body cavity by the retractor penis muscle creating an “S” shaped sigmoid flexure in the penile shaft. Upon sexual excitement the retractor penis muscle relaxes and extends the penis in preparation for intromission.

Spermatogenesis

The Rate of Spermatogenesis in the Ram

Rams achieve puberty between 5 and 12 months of age depending on breed and season of birth. Spermatogenesis occurs in the seminiferous tubules of testes – about 7000 m (m) of them in each testis of the ram (Setchell, 1984). As in other species, ram spermatogenesis is divided into proliferative/mitotic and meiotic phases, and a haploid, post-meiotic phase. Development of a single sperm from the first mitotic division of a spermatogonium until it reaches the center of the seminiferous tubules takes 31 days. It then takes 3–4 days to pass through the tubules, out of testis, and into the epididymis. Sperm are matured in the epididymis and held in the cauda epididymis awaiting ejaculation. Each epididymis is approximately 50 m long. Transit of sperm through the epididymal duct takes 14 days with most of this interval spent within the cauda epididymis. Thus the total passage time from the original division of the spermatogonium to a mature sperm ready for ejaculation is 49 days.

Fig. 1 The dissected reproductive tract of a ram. Adapted from American Sheep Industry Association, 2015. Sheep Production Handbook, vol. 8. Centennial, CO: American Sheep Industry Association.

The rate of sperm production can be determined in various ways. One is to determine the number of sperm produced per gram testis per day as this estimation is reasonably constant regardless of the size of the testis. In comparison with bulls, dogs and stallions that have a relatively low sperm production ($10\text{--}19 \text{ million g}^{-1} \text{ day}^{-1}$), rams have a high sperm production of $20 \text{ million g}^{-1} \text{ day}^{-1}$, similar to that of boars (Amann, 2010). As testicle size and weight vary among sheep breeds, the daily sperm output of a ram is estimated between 5 and 9 billion (Amann, 2010).

Major Factors That Affect Sperm Production in Rams

The two most important factors that can affect the amount and quality of sperm produced are nutritional status (body condition) and the ability of the ram to regulate testicular temperature. While sperm production continues even in very thin rams, the amount and quality of sperm produced is sensitive to nutritional status, with testicle size (volume) being reduced during times of poor forage quality and availability. Rams are seasonal breeders and mating activities contribute to the loss of both the testicle volume and body weight (Fig. 2) (Masters and Fels, 1984). It was reported that feeding supplements to rams on poor pasture for a month before breeding can increase testicle size and subsequent sperm production by up to 100% (Lindsay, 1988). At the same time, overfeeding can have a detrimental effect on sperm production. Overfeeding also reduces the numbers of years a ram lives and the number of ewes he mates per year. It can cause welfare issues due to joint and kidney problems.

For normal sperm production to occur, the testes are maintained at a temperature $4\text{--}6^\circ\text{C}$ below normal body temperature (38.5°C). The ram has numerous sweat glands in the skin of the scrotum and a system of muscles that raise or lower the testes for temperature regulation. If this temperature difference is reduced for extended periods resulting in excessive heating, then spermatogenesis is severely disrupted (Lindsay, 1988).

Puberty and Sexuality

Age at Sexual Maturity and Initial Breeding

Puberty is the age at which the ram's reproductive organs become functional, secondary sex characteristics develop, and he is ready to successfully mate ewes. Most ram lambs reach puberty between 5 and 8 months of age at 50%–60% of their mature weight. The onset of puberty is affected by breed, genetics, season of birth and nutrition. Ram lambs on a low plane of nutrition may not reach puberty until they are 12 months of age or older. Some breeds reach puberty earlier than other breeds, such as prolific breeds and hair sheep. Meat breeds tend to reach puberty earlier than wool breeds.

Age and growth of rams is an important consideration in maximizing flock fertility. Rams at puberty will have limited serving capacity because they are still growing. It is known that ejaculates collected shortly after puberty in rams contain a high proportion of abnormal sperm which exhibit poor motility.

Sexual Behavior

Sexual behavior or sex drive (libido) is controlled by androgens produced in the testis. It is also influenced by developmental events between conception and puberty, and is exhibited on a continuum. The hypothalamus in the brain coordinates information about the external and internal environment of the ram and produces gonadotropin-releasing hormone (GnRH), which causes the pituitary to produce luteinizing hormone (LH) and follicle stimulate hormone (FSH). Both LH and FSH are released in pulses into blood circulation to regulate testes function. The frequency of pulses changes seasonally, and is more important than the total amount released (Lindsay, 1988). LH and FSH stimulate steroidogenesis and testosterone production by testicular Leydig cells.

Testosterone regulates the ram's libido or desire to mate. Some breeds of rams show high libido continuously once they reach puberty. In other breeds, there is a marked decline in libido during the non-breeding season. Underfed and overfat rams may show reduced libido. A ram's desire to mate also decreases with age and disease conditions.

Fig. 2 The testicular volume of Merino rams is sensitive to nutrition. Adapted from Masters, D., Fels, H., 1984. Seasonal changes in the testicular size of grazing rams. *Anim. Prod. Aust.* 15, 444–447.

A sexual performance score of the ram (also known as ram libido score) is an attempt to quantify libido. It is generated based upon numbers of mounts and ejaculations in the presence of estrual ewes. Scores range from 1 to 6 with scores increasing from sexually inactive to highly sexually active. The sexual performance score is a highly repeatable and reliable predictor of the ram's libido under field conditions (Snowder *et al.*, 2004). Rams with high scores for sexual behavior can improve flock fertility during breeding. Like other traits, ram sexual performance is genetically influenced and serum testosterone level exhibit a high correlation ($r=0.90$) with sexual performance of rams during mating.

The Ram Effect

The "ram effect" is when non-cycling ewes are stimulated to ovulate by the sudden introduction of a novel ram. Rams produce chemical substances called pheromones, which are perceived by the ewe and can stimulate the onset of estrus in peripubertal ewes or ewes approaching the onset of the breeding season. For the ram effect to work, ewes should be isolated from rams for at least 6 weeks. Ewes must have no contact with rams by either sight, sound, or smell, which means that they must be separated by considerable distance. The great value of the ram effect is synchronization of estrus activity. In addition, when using a vasectomized or teaser ram, this can allow ewes to achieve several estrous cycles before the desired date of breeding, which will increase fertility (American Sheep Industry Association, 2015; Schoenian, 2016).

Seasonal Breeding

Like some goats and horses, many sheep breeders are seasonal breeders. Seasonal breeders optimize survival of young by synchronizing birth of offspring with favorable conditions including ambient temperature, weather conditions, and food and water availability. The breeding season of sheep in the northern hemisphere is fall and winter during shorter photoperiods (the period of time during the day when there is daylight), so sheep are known as short-day breeders (Gomez-Brunet *et al.*, 2008). Sheep breeds that originated in the northern hemisphere exhibit stronger seasonality than those that originated closer to the equator. The effects of photoperiod on estrous cyclicity are mediated by stimulation of the retina by light. During the fall, with reduced photoperiodic stimulation, melatonin release from the pineal gland increases. Increased melatonin results in onset of pulsatile release of GnRH and onset of reproductive cyclicity.

Unlike other seasonal breeders, the influence of day length on puberty onset in sheep is not equal in ram-lambs and ewe-lambs. In other words, the responsiveness to photoperiod is sexually differentiated in sheep. LH secretion in ewe-lambs is highly influenced by day length, whereas it is not in ram-lambs (Herbosa *et al.*, 1995). For mature sheep, ram breeding behavior is less seasonal compared with ewes even though testicle size, sperm production, and mating capacity of rams varies according to the season of the year, being highest during the normal fall breeding season. These changes are guided by the hypothalamic-pituitary-gonadal axis responding to photoperiod.

Ram Breeding Soundness Evaluation

A breeding soundness evaluation prior to ram introduction to ewes is essential to assess a ram's breeding capacity. However, careful consideration should also be given to nutritional management of rams so they do not enter the breeding season too fat or too thin. The purpose of the breeding soundness exam is to evaluate a ram's potential breeding ability. Approximately 10%–15% of rams have low fertility and low libido. The breeding soundness evaluation, which should be conducted by a veterinarian or trained technician, consists of three parts: physical examination of the ram, semen evaluation and breeding capacity test.

Physical examination of the ram should include palpation of the testicles, epididymis and examination of the penis in addition to visual appraisal of feet, legs, eyes, jaws and body condition. We focus here only on the importance of testicle size. A detailed guideline for ovine breeding soundness examination can be found in the American Sheep Industry Association (2015).

Testicle Size

Testicle size is a good indication of a ram's fertility and varies with season and body condition. Sperm production is positively correlated to testicle size. Testicle size is usually estimated by measuring scrotal circumference (SC) in centimeters (cm) (Foster *et al.*, 1989). The recommended SC minimums for ram lambs and mature meat-type rams are listed in Table 1 but will differ somewhat by breed.

Scrotal circumference and testicle volume decrease dramatically during the breeding season when rams are sexually active. This is often associated with a substantial decline in the body weight of the ram because of its mating activity (Gordon, 1997). It has been reported that rams with small testes are less fertile than those with larger testes in field mating due to production of fewer sperm (Gherardi *et al.*, 1980). However, there was no difference in the semen quality between rams with large and those with small testes (Gordon, 1997).

Semen Evaluation

Semen should be evaluated for sperm concentration, motility, morphology, and white blood cells. Motility is the percentage of spermatozoa showing forward progressive movement. The minimum acceptable standards are $\geq 30\%$ motile and $\geq 50\%$ normal

Table 1 Scrotal circumference guidelines in rams

Age of rams	Questionable	Satisfactory	Exceptional
Ram lambs, 8–14 months	<30	30–36	>36
Mature ram, >14 months	<32	32–40	>40

Source: Reproduced from American Sheep Industry Association, 2015. Sheep Production Handbook, vol. 8. Centennial, CO: American Sheep Industry Association.

morphology. Semen of an exceptional ram should contain >70% motile sperm with >80% normal morphology. The presence of white blood cells in the semen is an indication of infection (e.g., epididymitis). To reduce the occurrence of epididymitis, a serological test is recommended for *Brucella ovis*, which causes epididymitis. A positive test usually renders a ram unsatisfactory as a breeder.

Breeding Capacity

Breeding capacity refers to the number of ewes that a ram can mate and still achieve high fertility within a short breeding interval. It is not only a function of testicle size, semen quality and sperm production, but also depends upon sex drive, mating behavior and serving capacity of the ram. Serving capacity refers to the total number of times a ram can successfully breed the same or different ewes during a heat cycle. Serving capacity affects conception rate in the ewe in several ways. First, under continuous mating systems and at lower ram: ewe ratios (1:100), rams ejaculate fewer sperm than are optimally needed for high conception rates. Second, rams exhibit preference for mating with certain females, inseminating preferred ewes several times at the expenses of other ewes in estrus on any given day. Third, a dominate ewe can prevent a submissive ram from mating with other ewes in estrus. Finally, when ewes are synchronized in estrus by hormonal treatment a greater number of rams will be needed to achieve optimal fertility in a short breeding interval (American Sheep Industry Association, 2015). The working ram shows definite patterns of sexual behavior towards the ewe including genital sniffing, foreleg kick, vocalization, chin resting and mounting. More intensive screening can be done by pen mating test of rams exposed to several ewes that have been synchronized in estrus (American Sheep Industry Association, 2015).

The recommended ram: ewe ratios are 1:15–30 for well-matured ram lambs, 1:25–50 for yearling to five year old rams. However, in some western sheep production systems, the ram: ewe ratio can be as low as 1:100. The ability of rams to successfully inseminate ewes depends on the physical condition of the ram and the ambient temperature, sex drive, topography and area of pasture. For 6 year old and older rams, there is no recommendation of ram: ewe ratios as these rams are mainly suited for pasture or hand breeding only depending on the physical condition of the ram.

Failure to identify low-performance rams can result in a longer lambing season and possibly fewer lambs per ewe. However, failure to identify high-performance rams can result in underutilization of ram power. So, it is important to evaluate the ram breeding capacity before the main breeding season. The simplest way is by observing breeding performance and calculating sexual performance score (see above) as rams are exposed to ewes.

Artificial Insemination

Artificial insemination (AI) is a management tool that requires collection of semen from the male and depositing it into (inseminate) the female. It is estimated that more than 60 million ewes are artificially inseminated each year, although this represents a very small portion of the total ewes worldwide. A major advantage for using an AI program is the potential for genetic gains from more extensive use of superior sires. As discussed earlier, in a seasonal breeding system, a ram can breed approximately 50 to 100 ewes per year, whereas in the AI program, one ram can be used to inseminate thousands of ewes. In controlled-breeding and large-scale estrus-synchronization programs, AI is an essential component. There are some limitations to more widespread adoption of AI in the sheep industry. Primary among them has been the difficulty in passing an insemination pipette through the sheep cervix (especially with primiparous ewes), the limited options for synchronizing estrus, and the lower conception using frozen-thawed semen.

Collection and Evaluation of Semen

An artificial vagina is used most commonly for collection of ram semen. The semen can also be collected by electroejaculation, although this method is less reliable and the collected specimens vary in quality and quantity, and can be contaminated with urine. Normally 2–3 ejaculates are collected from a ram in a day. The volume of semen collected with the artificial vagina is 0.5–2.0 mL, and the concentration of the spermatozoa is $2.5\text{--}6 \times 10^9 \text{ mL}^{-1}$. Semen obtained by electroejaculation generally is of larger volume but lower concentration. Immediately after collection, the semen is assessed for color, volume, concentration of sperm, sperm motility and morphology, percent live sperm, and contamination.

Semen handling is crucial for the sperm cell viability and quality. High temperatures of 39°C or greater induce the acrosome reaction, resulting in greater proportion of dead or damaged sperm. Sudden decreases in temperature, particularly in the 5 to

18°C range, can cause irreversible loss of cell viability. Unnecessary delays from time of collection to AI of undiluted semen can be detrimental to the quality of the sample. However, controlled, slow cooling of diluted semen for extended term use does not seriously reduce sperm viability or fertilization capacity (American Sheep Industry Association, 2015).

Extension of Semen

Once semen evaluation is completed, the sample can be processed by extending or diluting, packaging, and storing. Semen may be diluted up to 10-fold, depending on the initial concentration, the processing and storage method, and whether the semen will be used fresh, chilled, or frozen-thawed. Most semen extenders have a buffered egg yolk base and cryoprotectants such as glycerol. These extenders can be used for semen destined to be used fresh or frozen. The number of motile sperm and the volume of an insemination dose for the ewe depends on the site of insemination and the method of processing. For vaginal insemination, 0.2 mL with a minimum of 1.5×10^8 motile spermatozoa is used; for cervical insemination, 0.05–0.2 mL is used with 1×10^8 , 1.5×10^8 , and 1.8×10^8 sperm of fresh, liquid-stored, and frozen-thawed semen, respectively. Intrauterine insemination by laparoscopy requires 0.08–0.25 mL (with a total of 2×10^7 motile sperm) into each uterine horn (Menzies, 2016).

Storage of Semen

Following the dilution of the semen, it may be prepared for short- and long-term storage. For short-term storage up to 24 h, the extended semen should be slowly cooled to 2–5°C over a 1.5–2 h interval and held at this temperature. Fertility decreases rapidly after 24 h and is low by 48 h. Long-term storage of semen requires that the samples be stored frozen in liquid nitrogen (–196°C). The extended semen is usually packaged in 0.25 or 0.5 mL straws. Sperm motility after thawing varies among rams and processing batches. Use of frozen-thawed semen may result in lambing rates of 50% with cervical insemination and 50%–80% with intrauterine insemination.

Insemination

Ewes can be inseminated either into the vagina, the cervix (cervical insemination) or into the uterus (intrauterine insemination). Extended fresh or chilled semen can be placed into the vagina or cervix, and extended fresh, chilled, or frozen-thawed semen can be placed into the uterus. The optimal time for insemination with fresh or chilled semen is 12–18 h after the onset of estrus. Ewes exhibit estrus for about 30 h and ovulate near the end of estrus.

Conclusions

Rams are seasonal breeders that have large testes in comparison with other mammalian species. Testicle size is estimated by measuring scrotal circumference, which is a good indication of a ram's sperm producing ability and varies with season, body condition and mating activity. A breeding soundness evaluation prior to ram introduction to ewes is critical to assess a ram's breeding capacity. In a seasonal breeding system, a ram can breed up to 100 ewes per year. In an AI program, one ram can be used to inseminate thousands of ewes. However, artificial insemination is not popular in the sheep industry because of the difficulty in passing an insemination pipette through the sheep cervix, the limited options for synchronizing estrus, and the lower conception rate using frozen-thawed semen.

Introduction

Male fertility depends on the continuous production of sperm by the testes, comprising a process of cellular events, called spermatogenesis. Spermatogenesis is a complex process consisting of stem-cell proliferation and self-renewal, meiotic divisions, and several steps of cell differentiation that ultimately result in the production of millions of motile gametes daily. This process is highly dependent of the presence of sufficient amounts of testosterone (T) produced by the interstitial Leydig cells (LC) as well as on the pituitary synthesis and release of the gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH specifically targets the Sertoli cells (SC) within the seminiferous tubules. SC are nursing cells that are indispensable for the normal progression of spermatogenesis. LH is responsible for the development of the adult LC population as well as stimulation of LC T production. Insufficient T production will hamper the progression of meiosis and can thus severely affect spermatogenesis.

Defects at any stage of spermatogenesis, as well as reproductive tract obstruction, inflammation and other sexual disorders may all contribute to male infertility, causing a significant distress to couples trying to conceive. Fertility problems affect up to 20% of all couples in Western societies, whereby nearly half of these involve a male factor. Environmental factors, lifestyle, and genetics all seem to be involved in the pathogenesis of semen anomalies, though in most cases the exact cause and underlying mechanisms of infertility remain unknown. It is speculated that in the coming decades infertility rates will further increase, bringing an additional burden on fertility clinics and raising costs of health care systems (Agarwal *et al.*, 2015).

Assisted reproductive technologies, such as *in vitro* fertilization (IVF) are most commonly used as treatments of male infertility. The development of the so-called intracytoplasmic sperm injection technique, or ICSI, in which a single sperm is injected directly into an egg, has enabled biological offspring even in cases of severe male infertility. This and other treatments are, although relatively efficient, only a means to circumvent rather than treat male infertility. Moreover, assisted reproductive techniques rely on the presence of sperm cells in the ejaculate or within the testis. With the increasing survival rates of male cancer patients that have undergone chemotherapy and/or irradiation, a new category of infertile patients becomes in search of treatment; patients in whom the testis is depleted of sperm. To develop novel treatments to help patients with the wide variety of infertility causes that is observed, a profound basal knowledge on spermatogenesis and testis function is required, coupled with the understanding of the triggers and processes leading to infertility (Cooke and Saunders, 2002).

The purpose of this article is to provide an overview of selected rodent models that have significantly contributed to our understanding of male fertility problems and consequently in their treatment.

Purpose of Animal Models

Since the beginning of 20th century, an enormous progress has been made in the field of male reproduction. Attempts to fill the existing knowledge gaps have resulted in an array of different *in vivo* and *in vitro* model systems, developed as tools to study spermatogenesis and testis function, each of them with specific advantages and disadvantages. From an ethical point of view, cell culture, or *in vitro* models are the preferred choice of research method and to date two models have been developed that are able to provide complete spermatogenesis, namely tissue culture with or without germ cell transplantation and 3D germ cell culture. In the three-dimensional culture systems, comprising of LC, SC, peritubular and spermatogonial stem cells (SSCs), SSC can differentiate into post-meiotic spermatids, albeit with a very low efficiency. Despite the huge progress made in mimicking the intricate spatial organization of the testis, the optimal endocrine and paracrine stimulations in these cultures remain largely unknown and thus present limitations for *in vitro* studies (Dores *et al.*, 2012). Nevertheless, such culture systems hold a great potential for studies trying to unravel the regulation of sperm differentiation as well as to study gene expression of each individual testicular cell type at different stages of spermatogenesis. Once developed for clinical use, they can contribute to much needed options for fertility treatment of infertile male patients. As an example, germ cells in many patients with non-obstructive azoospermia are malformed or underdeveloped, which makes them unsuitable for current IVF treatment. Culturing SSC of these patients under a controlled *in vitro* environment may lead to appropriate germ cell maturation and development of viable spermatids, suitable for IVF. Even though extremely desirable, the path to achieving complete and functional human spermatogenesis under *in vitro* conditions might still be a long and difficult one. Even if complete functional spermatogenesis is achieved, insight needs to be obtained in potential imprinting effects of the *in vitro* conditions, which may have undesirable consequences in the long term. Because of the lack of effective *in vitro* spermatogenesis models, rodent models can provide us a much-needed way forward to better mechanistic understanding of spermatogenesis.

Animal models have contributed much to our understanding of physiological processes not only in reproductive biology but also in biomedical sciences in general. Due to their physiological and genetic similarities with humans, rodents are one of the most commonly used model organisms and most of our knowledge on male reproduction indeed arises from studies performed on mice and rats. There are several reasons for the usefulness of rodent models in male reproductive biology. Firstly,

spermatogenesis in rodents and humans is highly comparable. Secondly, rodents have a relatively short reproductive cycle with large litters; but most importantly, with the introduction of genomic technologies in mice, the mouse genome became extremely easy to manipulate. Next to the more classical rodent models, the advancement of techniques such as gene targeting and homologous recombination lead to unique models for elucidating phenotypic effects caused by specific genes.

Up to date, at least 400 different mutant mouse models with mutations in fertility-related genes have been described, the majority of these being whole body or cell type specific gene silencing or overexpression models. Also, mutated alleles can be introduced. However, the use of genetically modified models does not come without limitations. Whole body gene silencing or overexpression can result in phenotypic defects in other organs, which may have a confounding influence on the effects observed in the tissue of interest, the testis. Cell-type-specific gene silencing or overexpression is usually a preferable option, as it eliminates many of the side effects from whole body gene silencing or overexpression. Furthermore, inducible promoters can be used, which are especially relevant to circumvent developmental effects. However, such models may not always be available due to the absence of cell-type unique promoters, and besides the generation of new models requires a considerable amount of time and costs.

Due to phenotypic and genetic robustness of organisms, gene silencing models often display so-called compensatory mechanisms. This means that a system can withstand a certain amount of change, caused by intrinsic or extrinsic factors while still function normally. There are two ways in which an organism can compensate for a missing protein: either through genetic buffering, with an alternative pathway taking over, or through genetic redundancy, where a given function of the deleted gene is redundantly encoded by other gene(s). Both mechanisms can efficiently mask the phenotypic effects of the mutation (Barbaric *et al.*, 2007).

In addition to the silencing of a specific gene, it is also possible to introduce specific mutations into the mouse genome. This makes it possible to create mouse models that carry specific, known mutations related to, for instance, human male infertility, allowing an in depth study of the pathway along which such a mutation influences fertility, thus contributing to a possible treatment. Models with gene mutations have, however, a serious limitation due to the large percentage of mice suffering from unexpected embryonic/neonatal lethality, limiting the analysis of gene function in reproductively mature animals (Jamsai and O'Bryan, 2011). The use of inducible promoters may circumvent this, since the mutated genes can be activated in later developmental stages.

In overexpression mouse models, phenotypic defects as a consequence of tissue specific or ectopic (over)expression of a gene can be studied *in vivo*. In the newer models, transgenesis is targeted at specific loci (e.g., Rosa26) for ubiquitous expression and the expression level of the transgene can, among others be influenced by the transgene copy number (Jamsai and O'Bryan, 2011).

An emerging possible cause of fertility problems in males that has received increasing attention, is the increasing exposure to endocrine disrupting chemicals (EDCs) that may through their androgenic or estrogenic action interfere with normal gonadal development during pregnancy (Wang *et al.*, 2017). Rodent models have significantly contributed to our knowledge on especially the consequences of EDC exposure during pregnancy and its consequences for fetal and postnatal gonadal development and fertility in adulthood.

In the following section a selection of rodent models and their contribution to our understanding and possible treatment of male fertility problems will be discussed.

Application of Rodent Models

Spermatogonial Stem Cell Transplantation

SSCs are unipotent stem cells, responsible for the maintenance of the continuous production of sperm throughout man's life. From the pool of SSC located at the basement membrane of the seminiferous tubules interconnected pairs of daughter cells can initiate differentiation to become mature spermatozoa. A fine balance between self-renewal and differentiation of SSCs is dependent on their close association with the surrounding somatic SC and needs to be carefully orchestrated by underlying signaling pathways. Knowledge of these regulatory cues is crucial to understand the initiation of spermatogenesis, SSCs renewal after cytotoxic insult, and possible treatments of infertility.

In the early 1990s, the understanding of SSC characteristics was based largely on morphological studies. There was a clear consent that both, endocrine and paracrine signaling molecules were involved in the regulation of SSC proliferation and spermatogonial differentiation, but very little was known about the biochemical and molecular properties of the process. One of the common techniques to study the behavior of SSCs at that time was a depletion of the seminiferous epithelium in rodent testes by cytotoxic agents. Radiation was one of such agents commonly used to differentially kill rapidly dividing cells such as differentiating spermatogonia, while leaving the SSC population largely intact. Subsequent repopulation of the seminiferous epithelium was due to proliferation and differentiation of the remaining SSCs, which made it possible to trace the entire progeny of an individual stem cell (Meistrich and Van Beek, 1993).

In 1994, an enormous progression in our understanding of SSCs occurred when Brinster and colleagues reported the first successful mouse-to-mouse SSCs transplantation, leading to a viable progeny from a previously sterile recipient mouse. The procedure comprised of isolation of SSC from the testes of donor mice, successful *in vitro* maintenance of the cells, followed by their transplantation into the seminiferous tubules of the previously established infertile mice. Infertility of recipient mice was ensured experimentally by cytotoxic treatment, using busulfan, which completely destroyed SSC's. Following microinjection, donor SSCs were able to attach to SC and colonize the basal membrane from the luminal side, where they clonally expanded and subsequently formed patchy repopulated areas. These authors showed, for the first time, that SSC transplantation can establish normal

spermatogenesis within donor's testis and, moreover, produce fully functional spermatozoa that restore the fertility of the donor (Brinster and Zimmermann, 1994).

The most critical phase during homing of newly transplanted spermatogonia is the migration towards the seminiferous tubule basement membrane, especially the crossing of the SC tight junction barrier. The formation of this blood-testis barrier in mouse testis occurs early in the postnatal period, approximately 10 to 12 days pp, when proliferation of SC ceases. SSC transplantation performed in immature mouse pups shows that colonization of the recipient testis is much more efficient when SC tight junctions are not yet formed. The number of colonies generated in recipient pup's testis was 5–10 times greater as when compared with adult recipients. These observations suggest that seminiferous tubules of an immature testis may possess a much more favorable microenvironment for transplanted SSC colonization and expansion, regardless of the donor's age (Shinohara *et al.*, 2001; Kanatsu-Shinohara and Shinohara, 2013).

Successful development of the mouse SSC transplantation assay together with the development of a functional *in vitro* system for SSC culturing initiated active research in the field of fundamental aspects of spermatogenesis, as well as in stem cell biology. Several xenogeneic SSC transplantation studies that followed the initial mouse-to-mouse transplantation revealed not only the extent of evolutionary conservation in regulation of spermatogenesis between species, but also the extent of SSC autonomy in proliferation and differentiation. Transplantation of rat SSCs into testes of immunodeficient mice resulted in the establishment of complete rat spermatogenesis within mouse seminiferous tubules. Mouse SC were entirely capable of supporting rat stem cells, while the timing and organizational pattern of spermatogenesis appeared to be intrinsic to the transplanted germ cells. Thus, the entire process of spermatogenesis initiated from rat SSCs still required 52 days and not 35 days, as in mouse spermatogenesis, despite being controlled by mouse somatic cells (Brinster, 2002).

The stem cell transplantation assay further provided an extremely useful approach for studies aiming at unraveling the regulatory pathways within the SSC niche. The SSC niche is a specialized microenvironment consisting of supporting somatic SC, LC, and peritubular-myoid cells, extracellular matrix components, and several signaling molecules produced by the niche cells, which jointly regulate the SSC identity and capacity of the niche. Polarized SC provide physical support for SSCs and differentiating germ cells, supply nutrients and emit external signals for initiation and coordination of the complex process of spermatogenesis. They are also responsible for sustaining the blood-testis barrier and the segregation of the seminiferous epithelium into a basal and an adluminal part. With the development of functional SSC transplantation technique, the testicular SSC niche became an ideal model to study.

During the last decade, our understanding of the regulation and coordination within the mammalian SSC niche on a molecular level has progressed immensely. The discovery of glial cell line-derived neurotrophic factor (GDNF) secreted by SC has unexpectedly identified one of the most important paracrine molecules involved in SSC self-renewal in the mouse. The GDNF signaling pathway is triggered through the binding to a RET receptor tyrosine kinase and GDNF family receptor- α 1 (GFR α 1) complex, which in turn activates downstream intracellular responses. Using mouse models, *Gdnf* under- or overexpression studies have helped us understand its role in the lineage determination and maintenance of undifferentiated spermatogonia (Hofmann, 2008). For example, *Gdnf* targeted overexpression has been shown to result in rapidly proliferating spermatogonia, leading to testicular germ-cell tumor formation.

Production of GDNF in SC is influenced by FHS, growth factors and cytokines, stimulating *Gdnf* expression throughout life. Its constant levels are required for the maintenance of undifferentiated spermatogonia in the germ cell niche. A drop in GDNF levels, together with a surge of retinoic acid represents a signal that is sufficient for initiation of differentiation in adjacent spermatogonia. While GDNF is indisputably required for self-renewal of mouse SSCs, several other factors are involved in defining a SSC niche.

Recent advances in SSC cryopreservation, *in vitro* propagation and transplantation hold a potentially valuable clinical application; the techniques may offer a successful treatment option for infertility of young male cancer patients who have previously undergone an aggressive treatment, such as chemotherapy or irradiation, often resulting in a complete and permanent depletion of pre-meiotic germ cells. As the spontaneous recovery of spermatogenesis in oncological patients is generally not observed regardless of the patient's age, assisted reproductive techniques are the only treatment option available to father biological children. Semen cryopreservation before therapy is an established clinical procedure and a solution to preserve the fertility of adult cancer patients. Still, the chances of achieving a successful fertilization and live delivery through assisted *in vitro* fertilization in male cancer survivors are as low as 22%. Semen cryopreservation is not an option in pre-pubertal boys, in which the onset of sperm production has not yet begun. The isolation and cryopreservation of SSCs before the beginning of cancer treatment with the subsequent re-injection of SSC after the therapy is thus a promising technique that may allow natural conception even in immature oncological patients (Ehmcke *et al.*, 2006; Mulder *et al.*, 2016).

The EDS Model in Understanding Leydig Cell Development

In the early 1980s, largely by chance, rats treated with the glutathione-dependent alkylating agent ethane-1,2-dimethyl sulphate (EDS) became a prime model for studies aiming at understanding the formation of the LC population in the adult rat testis and the underlying developmental cues. Initial studies showed that a single dose of EDS was able to destroy the entire population of LC while leaving the remaining testicular cells intact. Within 3 days after the administration of the toxicant, the complete LC population was degenerated through apoptosis. For approximately 2 weeks after treatment, the testicular interstitium remained depleted of LC. Concomitantly with LC apoptosis, the testosterone production ceased and was completely inhibited for 2–3 weeks (reviewed in Teerds and Rijntjes, 2007).

The mechanism by which EDS exerts its cytotoxic effect upon LC was elucidated many years later when it became clear that EDS compromises the steroid production pathway by disrupting the mitochondrial electrochemical potential, affecting among others steroidogenesis acute regulatory protein (StAR) import across the mitochondrial membrane. Since StAR is responsible for the transfer of cholesterol from the mitochondrial outer membrane to the mitochondrial inner membrane, where it then is cleaved into pregnenolone, its absence severely compromises steroidogenesis (reviewed in [Teerds and Rijntjes, 2007](#), chapters 36, 37).

One of the important findings of the EDS model was the observation, that stem LC (SLC) persist throughout adulthood and as such hold the potential to regenerate the entire LC population. The origin of adult LC was a matter of dispute for a long time, but more recent studies have shown that SLC are mainly located in close vicinity of the seminiferous tubules, and to a lesser degree around the interstitial blood vessels. The regeneration of the adult LC population after EDS in many aspects closely mirrors the initial establishment of the adult population in the developing testis, thus providing a good model to study this process. LC ablation has also proven to be extremely informative when it comes to understanding androgen function in the testis, especially with regards to SC functioning and maintenance of spermatogenesis. Interestingly, several studies have shown that spermatogenesis remains largely undisrupted if EDS exposed animals are simultaneously treated with sufficient doses of androgen. This suggests that, when it comes to spermatogenesis, androgen production is by far the most important role of adult LC.

The EDS-treated rat model is one of several cell ablation animal models used in male reproductive research. Various testis-specific cell types, for example, germ cells, macrophages, and SC, have all been successfully ablated using different approaches. The major criticism of this method relates to its unpredictability, as the elimination of an entire cell population disrupts an innumerable amount of signaling pathways within the testis tissue and beyond. While this is indeed the case with such a severe and radical approach, the method is however not meant to elucidate specific mechanisms or signaling pathways within the testis. Rather it is a powerful tool to reveal the role of a specific cellular type in the development and functioning of the tissue ([Smith et al., 2015](#)).

Rodents as Model for Testicular Dysgenesis Syndrome

Several adverse trends in male reproductive health such as the increasing incidence of undescended testis and hypospadias, subnormal sperm count, and testicular germ cancer, all seem to be related to one underlying entity called testicular dysgenesis syndrome (TDS). Even though some of these disorders usually manifest later in life, abnormalities are thought to start to accumulate already during fetal development and share several pregnancy-associated risk factors. Based on the prevalence of these disorders in Western countries, environmental and/or lifestyle factors are speculated to be involved in its pathogenesis, albeit with an important contribution of genetic predisposition.

It has been hypothesized that TDS may arise from several different prenatal primary causes, which lead to LC and/or SC malfunctioning during sexual maturation, abnormal germ cell differentiation, and androgen insufficiency. All these defects may result in immediate symptoms, such as the above mentioned hypospadias, undescended testes or increase disease susceptibility later in life. Testing this hypothesis has proven difficult due to relative inaccessibility of the fetal testis at early stages of gonadal sex differentiation as well as long periods required for development of potential adverse health outcomes later in life. With the exception of epidemiological studies and testicular biopsies of TDS patients, clinical studies on the development of TDS are very difficult to perform. In such cases, rodent models can contribute greatly to our understanding of the pathogenesis of the disease.

A model of TDS was first proposed when male offspring of rats exposed in utero to di-n-butyl phthalate (DBP), were shown to display symptoms very similar to those of TDS. In essence they exhibited all symptoms of TDS with the exception of testicular germ cell cancer, for which no suitable animal model has been reported so far. DBP is a commercially important phthalate ester with anti-androgenic properties, used for production of soft plastics for a variety of commercial products. Prenatally affected male rats exhibit focal areas of dysgenic tubules, malformed seminiferous tubules, impaired LC functioning, and abnormal SC proliferation, consistent with the proposed hypothesis of TDS development in men. Studies performed in the DBP-induced TDS rat model as well as animals treated with the nonsteroidal antiandrogen flutamide, are helping to dissect the underlying mechanisms that lead to male reproductive disorders and provide some important information about the critical timing for initiation of dysgenesis during fetal development ([Skakkebaek et al., 2001](#); [Sharpe and Skakkebaek, 2008](#)). An important finding is the observation that prenatal blockade of androgen action during a specific fetal programming window can induce hypospadias, cryptorchidism, and altered penile length. Several studies have confirmed that androgen-driven masculinization of the gonads is indeed mediated by a common early programming window, which occurs before maximal androgen secretion. The existence of such programming window in humans has not been confirmed yet, but based on this rat model it is speculated to occur between 8 and 14 wk of gestation ([Wohlfahrt-Veje et al., 2009](#)).

The inhibition of testosterone production during the prenatal and early postnatal period results in a substantial reduction in SC numbers, indicating the essential role of androgens in SC proliferation during this period. This finding was rather unexpected, as SC in the fetal human and rat testis do not express nuclear androgen receptors (AR). It seems that the effects of androgens on SC during this phase of testicular development are mediated by another testicular cell type, presumably AR-positive peritubular-myoid cells. Low SC numbers are one of the main determinants of low sperm count in adult men, therefore reduced androgen levels and/or impaired androgen signaling in the fetal testis might be involved in the etiology of TDS-related disorders ([Skakkebaek et al., 2001](#)).

Despite all the knowledge we have gained from animal models and clinical research, it is still not clear to what extent environmental and lifestyle exposures participate in the development of testicular dysgenesis. Maternal lifestyle during pregnancy, including obesity, alcohol consumption and smoking, might all influence fetal sexual development. Interestingly, smoking during pregnancy has been shown to have more pronounced adverse effects on male fertility than man's own smoking in adulthood.

Moreover, people living in modern societies are exposed to numerous man-made chemicals on a daily basis, which have been implicated to influence normal fetal development. There is an accumulating body of evidence suggesting that prenatal exposure to endocrine-disrupting chemicals, such as phthalates, pesticides, and dioxins, is likely to affect normal male fetal reproductive development. If ever confirmed that TDS-related abnormalities can be attributed to modern lifestyle and environmental factors, most cases of TDS will in principle be preventable. However, proving the hypothesis of causal relationship between genetic predisposition, environmental chemicals and fetal testis development will certainly not be an easy task (Juul *et al.*, 2014).

Conclusion

- Rodent models have contributed much to our understanding of physiological processes in reproductive biology.
- The mouse model of SSC transplantation has not only increased our understanding of the complexity of spermatogonial proliferation and differentiation, but also offers future opportunities for fertility preservation in prepubertal and adult oncological patients.
- The ethane-1,2-dimethylsulphonate-treated (EDS) rat model is one of several cell specific ablation animal models that has contributed significantly to our understanding of the ontogeny of the LC lineage, and androgen function in the testis especially with regard to SC functioning and maintenance of spermatogenesis.
- Rodent models have made clear that prenatal blockade of androgen action during a specific programming window can induce cryptorchidism, hypospadias and altered penile length, underlying TDS. Based on clinical evidence, it is speculated that such a programming window will also exist in humans.

Male Dog Overview

Mushtaq A Memon, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Dog is considered man's best friend, whether it is for companionship, helping herding cattle, guarding home or helping a blind to find his way. Due to some similarities between human and dog physiology, dog has provided beneficial information as a model for human disease investigation and finding cure for many diseases (Harkey *et al.*, 2013). Reproductive biologists and scientists have been equally fascinated with the unique reproductive physiology and anatomy of the dog.

Puberty or Sexual Maturity

Puberty in the dog refers to first appearance of sperm in the ejaculate, and the sexual desire and the ability to copulate (Johnston *et al.*, 2001). Most of the male dogs of various breeds reach puberty at about 80% of their adult body weight. Large breed dogs, e.g., Great Dane may reach sexual maturity about 2-year age, whereas small breed such as Dachshund may reach puberty at about 6-month age. To confirm if the dog has reached puberty, breeding with a female or collecting semen for presence of sperm is recommended.

Gender Determination

Gender differentiation occurs at embryonic level, and it is dependent on the type of chromosomes. All dogs have 78 chromosomes, of which 2 are sex chromosomes. In the female, the sex chromosomes are XX, whereas in the male have XY. At embryonic stage, the mullerian and wolffian ducts form the female and male reproductive tract, respectively. With the help of Sry gene on the Y chromosome influences the indifferent gonad to form into testis. The testis produces mullerian-inhibiting factor which inhibits development of female reproductive system (Moore and Lambert, 1963; Meyers-Wallen and Patterson, 1986; Johnston *et al.*, 2001).

Reproductive Anatomy and Physiology

The reproductive system of the male dog consists two testes and epididymides enclosed in scrotum, the prostate gland, and penis. Palpation of the testes is performed to confirm that both testes are present in the scrotum, and they are normal size and consistency (Gradil *et al.*, 2006; Memon, 2007). The scrotum in the dog is sparsely covered with hair, feel relatively smooth and soft, having skin that is freely movable over the testes, non-painful on touch and uniform thickness (Feldman and Nelson, 2004). Testicular size varies with body weight in the dog. Body weight is positively correlated testicular weight, volume, and testicular width (Woodall and Johnstone, 1988; Eilts *et al.*, 1993). Even though there is limited information available regarding testicular size in different breeds (Table 1), but most experts agree that there is positive correlation between testicular size and sperm production.

The testes perform two functions, spermatogenesis and production of hormones. The endocrine control of spermatogenesis is governed by the neuroendocrine activity along the hypothalamic-pituitary-testicular axis (Ramaswamy and Weinbauer, 2014). The Leydig or interstitial cells secrete testosterone (T) hormone in response to luteinizing hormone (LH) stimulation. Inhibin and activin hormones are secreted by Sertoli cells, and T exert feedback on the pituitary, controlling secretion of the gonadotropins LH and follicle-stimulating hormone (FSH). Formation of androgen-binding protein in Sertoli cells is stimulated by FSH. Binding of T to androgen-binding protein maintains intratesticular T concentration necessary for spermatogenesis (Johnston *et al.*, 2001). Spermatogenesis take place in seminiferous tubules in the testes. Spermatogonia or immature sperm go through series of developmental cycles, which may take about 45 days to become mature spermatozoa. The sperm are transported from seminiferous tubules to rete testis, located in the middle part of the testes. The sperm then move from rete testes to head, body and finally reach tail of the

Table 1 Mean ($\pm$ sem) total scrotal width, sperm output and sperm counts for normal dogs of selected weight ranges

Body weight range lbs (Kgs)	Total scrotal width (mm)	Daily sperm output per dog $\times 10^6$	Sperm count in ejaculate ^a 10^6

epididymis. As sperm is transported through the epididymis, it goes thru various chemical and morphological changes necessary for sperm to gain capability of fertilization. The sperm transport thru epididymis may take about 15 days to complete. The sperm is stored in tail of the epididymis until ejaculated. Therefore, it takes about 60–62 days (Amann, 1989) from development of spermatogonia to spermatozoa (spermatogenesis - 45 days), and sperm transport and maturation in the epididymis (15 days).

Some unique features of dog reproductive anatomy include the presence of a bone in the penis and presence of only one accessory sex gland, the prostate.

The prostate gland is comprised of two lobes, enclosed by an outer layer of tissue and surrounds the urethra (Evans and Christensen, 1993). It produces seminal plasma; during ejaculation, the seminal plasma is secreted into the urethra to dilute the sperm. In prostatic epithelial cells, testosterone, produced by the Leydig cells of the testes, is converted by an enzyme, 5-alpha reductase to dihydrotestosterone (DHT), a much more active form of this hormone that regulates prostatic development and function.

Semen Collection

The most common semen collection technique is by digital manipulation of the penis. Semen may be collected with artificial vagina (AV) comprised of a latex rubber cone attached to a 15 mL calibrated plastic centrifuge tube (Reproduction Resources, Hebson, IL). Other technique is gloved hand and semen collection in color-coded Funnels (Minitube of America, Verona, WI).

The semen collection environment, collector's experience and dog's temperament influence the outcome of the collection. A 'door mate' or a carpet for 'good footing' for the male is helpful.

Most experienced dogs will ejaculate with simple hand stimulation, whereas in-experienced or younger dogs may require a teaser bitch in-heat. If a teaser bitch not familiar with the male, may require some time to 'get-to-know' each other. The semen collector, if right handed, kneels at the dog's left side and holds the AV with top folded in the left hand, and uses the right to move the prepuce up and down the shaft of the penis. Left-handed collectors may reverse the sides described here. At this time, many dogs will begin to thrust the penis in to the rubber cone, and the collector should then move the AV above the engorging bulbous glandis (Fig. 1) and keep firm, steady pressure around as much of the penis as possible to maintain the erection. If the male does not begin to thrust, the AV should be worked up on the penis in an up and down massaging motion to stimulate erection and ejaculation. If using the gloved hand/funnel technique (Fig. 2), the gloved hand is used instead of the AV, and all other steps are the same as discussed above.

Fig. 1 Normal erect penis of the dog. Note the engorged proximal portion, the bulbous glandis. Os penis (bone in the penis, not shown) provides rigidity to penis to penetrate in the female before erection. The bulbous glandis form rigid bulb during erection creating the copulatory lock between male and the female during breeding.

Fig. 2 Funnel technique for semen collection in the dog. The operator is holding the erected penis proximal to bulbus glandis, tip of the erected penis is directed in the funnel, and the ejaculate is collected in the attached tube. This techniques provides ease in changing the tubes to collect 3 semen fraction separately by different collecting tubes.

Consideration is given to when the dog was last collected as well as possible recent breedings and ejaculations, as these may affect results of semen collection and evaluation. Most dogs ejaculate the pre-sperm (clear) and sperm rich fraction (cloudy) of semen during the time of most rapid pelvic thrusting and then dismount and lift one hind leg as though trying to step over the bitch and achieve the tie. At this time, the penis is rotated at about 180 degrees and is directed caudally while still maintaining tight pressure around the bulbus glandis until the third prostatic fraction of semen is ejaculated. The prostatic fluid is ejaculated after a short pause. At the same time, anal contractions can be seen and rhythmic pulsations of the penile urethra can be felt by the collector. After a few mL of the prostatic fractions are collected, the AV may be removed. Let the dog ejaculate the rest of the prostatic fluid, which may take between 5 to 15 min. The teaser bitch (if used) may be removed from the collection area. Allow some time for the dog to lose his erection and retract the penis into the prepuce before leaving the collection area.

Prostate Examination

The prostate is the only accessory sex gland present in the dog and it contributes its secretion as part of the ejaculate. A lubricated gloved index finger is inserted in the rectum to feel the walnut-shaped, bi-lobed prostate on the floor of the pelvis. In medium to large size dogs, the examiner may have to push the ventral abdomen upward to facilitate feeling of the whole prostate gland.

Semen Evaluation

The semen sample or sperm-rich fraction is evaluated based upon color, sperm motility, sperm concentration, and percentage of morphological normal sperm. Additional semen tests (pH, cytology, presence of WBCs, alkaline phosphatase) are done in cases of infertility diagnosis of the dog. The color of normal semen should be cloudy to milky white.

Semen volume can be read from the calibrated collection tube. Semen volume varies with the breed, size of the dog and the amount of prostatic fluid collected

Sperm motility should be evaluated within a few minutes of semen collection. Place a drop of semen on a warm (37 degrees C) microscope slide, place a glass cover glass over the drop and examine under 100–200X magnification. The percentage of motile sperm are estimated, those moving in progressive forward manner. Sperm moving in circles or wiggling in one spot can indicate

Table 2 Characteristics of normal canine semen

Parameter	Normal values
First fraction	0.5–2.0 mL, clear
Second or sperm-rich fraction	1.0–4.0 mL, opalescent
Third fraction	2.0–50 mL, clear
Total ejaculate volume	2.5–60 mL
Sperm concentration	4–400×10 ⁶ /mL
Total sperm per ejaculate	300–2000×10 ⁶ /mL
Sperm motility	>70%
Normal morphology	>80%

In: Concannon, P.W., England, G., Verstegen, III J., Linde Forsberg, C., (Eds.), Recent Advances in Small Animal Reproduction. Ithaca NY: International Veterinary Information Service. Available at: <http://www.ivis.org/advances/Concannon/gradil/chapter.asp?LA=1>. (assessed 15.11.17).

chemical or cold shock to the semen. These sperm are considered mobile but are not motile (sperm moving in forward, progressive manner). It is desirable to examine 4 to 5 different microscopic fields, make an average of the fields to arrive the final percentage of sperm motility. Even though sperm motility is a subjective test, but it is a quick functional test, commonly used to assess semen quality. Other objective methods of semen evaluation include computer-assisted sperm motility and flow cytometry are available (Martinez, 2004).

Sperm concentration or sperm numbers are more important to count in whole ejaculate (total volume) than per milliliter of the semen, because total semen volume is going to depend upon how much prostate fluid is collected. Again, expensive automated semen analyzers are also available for this purpose (Martinez, 2004), but sperm count by hemocytometer is the most common technique used. A white blood cell unopette system (Becton Dickson, Ruthford, NJ) is used to process the semen sample for sperm count with hemocytometer (Johnston *et al.*, 2001). It utilizes a premeasured volume of diluent in a chamber into which a specified amount of semen is drawn. The semen sample is mixed gently and drawn into the capillary pipette of the Unopette, which holds 20 µL. Place the contents of the capillary pipette into the container of diluent according to the kit instructions. The diluted semen is mixed and is loaded into the 2 counting chambers of the hemocytometer and the sperm are counted under the microscope. The number of sperm counted×10⁶ is the concentration per mL. For the total number of sperm multiply concentration×volume. The total number of sperm for a small dog is reported as 400×10⁶; whereas the large dogs yield an ejaculate with around 1.4×10⁹ sperm (Amann, 1986).

Sperm morphology (normal and abnormal sperm) is assessed by examination of the stained slide of the semen. Smear of sperm-rich fraction of the semen is made, air-dried and stained with eosin-nigrosin (Rouge, 2004). One drop of semen and a similar sized drop of stain are placed on one end of a glass slide and the drops are mixed gently with a wooden applicator stick. A second slide is used as a spreader slide to draw out a thin film. The smear is air dried, and checked under the microscope. Other option is using Diff-Quick stain, the air-dried slide is immersed in each (total 3) solution for 5 min. Some prefer examining the semen wet mount slide. This technique requires placing 1–2 drops of semen in 1 mL buffered formol saline in a tube, the contents are mixed, and taken drop from the mixture, and placed on the microscope slide, cover glass is applied and examined under phase contrast microscope.

One to two hundred (100–200) sperm are examined using the oil-immersion (1000X) microscope objective. The smear must be thin enough to visualize individual sperm. Each sperm is classified as either: normal sperm; sperm showing a primary abnormality, which includes all sperm head abnormalities (e.g., micro or macro head), proximally coiled sperm tails, and proximal cytoplasmic droplets. The secondary sperm abnormalities are considered for sperm with detached heads, bent tails, and sperm with distal cytoplasmic droplets.

Primary abnormalities represent abnormalities that originated during spermatogenesis in the testes. Secondary abnormalities are believed to occur during epididymal transport and/or a result of improper semen sample handling.

Primary abnormalities should not exceed 20%; however, pregnancies have been achieved when the abnormalities exceeded this number. Most normal dogs, which ejaculate regularly, would have >200 million sperm in an ejaculate, of which over 80% are normal (Table 2).

The Male Cat

Emmanuel Fontaine, Royal Canin Canada, ON, Canada

© 2018 Elsevier Inc. All rights reserved.

Introduction

Just in the United States, recent surveys indicate that there are nearly 74 million of cats kept as pets. Their independent nature indeed seems like a great fit to our sedentary lifestyle. There is definitely no doubt: cats are on the rise.

Interestingly enough though, cats are very often mistaken as “smaller versions” of dogs. It is an easy parallel indeed. People – even veterinarians sometimes – easily assume both species “work” the same... This is obviously not true; they are both unique in their own way, and cats have specific features that set them apart; especially when it comes to the reproductive function.

This article focuses on the male cat. Having a good understanding of its reproductive physiology and specificities will come handy in many situations – and not only to veterinarians and veterinary staff. For instance, a pet owner might want to know when its male kitten will reach puberty. Somebody working or volunteering at a cat rescue or a humane society will be interested in knowing the consequences of neutering. A cat breeder will obviously want to know more about breeding behavior and breeding activity.

We have more and more answers – and solutions – to provide to all those questions we get from the field. There is indeed more and more research published on the reproductive function in male cats, driven by two things:

1. Cats are prolific animals and cat overpopulation is definitely a concern in many areas of the world, even in developed countries. More and more research is done on how to efficiently control their population via controlling their reproductive function;
2. There are 37 different felid species on Earth and the only one that is not endangered is the domestic cat. This makes it the perfect model in conservation biology. Several groups are therefore studying its reproductive function in order to build better strategies to help out wild felids in the field.

This article will give us an opportunity to review the specific reproductive characteristics of the male cat. We will describe its anatomy, its reproductive physiology as well as discuss neutering and most common reproductive disorders encountered in this species.

General Anatomy of the Male Cat Genital Tract

The male cat genital tract (see Fig. 1) is composed of:

1. The gonads:

The two testes of the adult cat are spherical to ovoid and are located in the scrotal sac ventral to the anus. This is where spermatogenesis occurs. The testes are also endocrine organs producing androgens and are the main source of testosterone in the cat. Testosterone is necessary for the development of secondary sex characteristics, such as the heavy jowls of male cats, and normal sex behavior.

The extra-abdominal localization of the testes is of great importance: in this position, the testes are submitted to a cooler temperature than the body's, which is a mandatory requirement for spermatogenesis to occur.

2. The epididymes:

These tubular anatomical structures are attached to the testis. This is where the spermatozoa will undergo maturation (spermiogenesis). Only after maturation do the spermatozoa have the ability to be mobile and fertilize and egg.

Fig. 1 Organization of the male cat genital tract.

In cats, this is also the only storage structure of the male gametes. Spermatozoa present in the ejaculate originate in fact from the caudal part of the epididymis (Parkinson, 2009).

1. Accessory glands:

Only two glands are found in the genital tract of a male cat: the prostate and the bulbo-urethral glands. The secretions of those glands play a role in the formation of the male's ejaculate.

2. A copulatory organ:

The penis is located inside the prepuce.

Some of the unique anatomical characteristics of the male cat genital tract are definitely worth noticing, and concern the testes and the penis.

The Testes

Testicular development starts at an early age, in fact even before birth during the embryonic and fetal phases. The testes will emerge caudally to the kidney and will then progressively migrate to reach the scrotum.

In cats, on the contrary to dogs, the testes are present in the scrotum right after the kittens are born (Johnston *et al.*, 2001).

However, because of their small size at this age, it is usually difficult – even not possible – to properly palpate and identify them in newborns. This will become easier as kittens get older and usually, both testes can be properly identified around the time of nutritional weaning, when the kittens are 4–4.5 weeks old.

Determining the sex of a newborn kitten might therefore be tricky. This is usually achieved by looking at the ano-genital distance (see Fig. 2). This distance is shorter in the male than in the female and will help differentiate both genders (Malandain, 2006).

The Penis

During its early formation, the penis adheres to the prepuce via a structure called the balanopreputial fold. Dissolution of this fold is an androgen-dependent event that occurs after birth in most mammals.

In male cats however, breakdown of this fold and resulting ability to completely protrude the penis from the prepuce occurs at 7–12 months of age, unless the cat is castrated prior to that time, in which case the adhesion persists.

The other particularity of the cat penis is that it carries penile spines. At about 9 weeks of age, elongated pits become evident on the surface of the glans penis, from which androgen-dependent penile spines (see Fig. 3) erupt between 9 and 13 weeks of age.

Fig. 2 Gender determination in newborn kittens based on the ano-genital distance.

Fig. 3 Penile spines.

In the adult intact male cat, the penis free end – the glans – is a 5–10 mm long conical structure directed caudally that contains a band of 120–150 of those androgen dependent penile spines in 6 to 8 circular rows. Following castration of the adult cat, spines regress rapidly, reaching hair-like structures in 5–6 weeks.

The presence of the penile spines is an easy clinical way to confirm testosterone production – and therefore presence of a testis -. This is an interesting clinical feature used often when the presence of an ectopic testis – which is the most common genital disorder seen in males of this species- is suspected in a male cat that is supposedly castrated (Fontbonne *et al.*, 2007).

The physiologic role of the spines in copulation is unknown; they have been proposed to provide sexual stimulation for the male or female, to impede withdrawal of the penis from the vagina (as they are directed towards the base of the penis) or to increase vaginal stimulation therefore favoring successful induction of ovulation.

Of interest also is the presence of an os penis, which presence seems to vary depending on the size of the cat. The os penis is 3–5 mm long and may be present inside the tip of the glans. In one study, the os penis was present in 3 of 9 medium size cats and 10 of 12 large size cats; no os penis was however found in kittens and small adult cats (Jackson, 1902).

Physiology of Reproduction in the Male Cat

Puberty

Earliest evidence of spermatogenesis in the cat occurs at approximately 20 weeks of age and spermatozoa are present when the testes exceed 1 g in combined weight.

Sperm may be ejaculated in semen of male kittens as young as 7 weeks of age, but the age at which mating begins varies with physical condition and body size, with average onset of puberty occurring at 8–10 months or at body weight of 2.5 kg, whichever occurs first.

It is interesting to note here that there is definitely a breed effect. While Persian cats and related breeds usually have a tendency to reach puberty later in their life (a male Persian might not properly breed before 2 years of age), Oriental breeds on the other hand are known to be rather precocious and might start breeding as early as 6 months of age (Malandain, 2006).

Seasonality

In the female cat, reproduction has a seasonal pattern that is influenced by the hormonal secretion of melatonin. While this has been well established in females, seasonality is however still a controversial topic in male cats.

Some studies have described a fall of libido during the winter months, associated with lower quantities of sperm cells in the ejaculate as well as an increased percentage of abnormal forms in the sperm (Tsutsui *et al.*, 2009).

One thing however remains: sperm cells are always found in the seminiferous tubules of the male cat's testes. Ejaculates containing fertile spermatozoa can be found all year long. Therefore, male cats definitely have the ability to breed throughout the year.

The limiting factor does not appear to be the tomcat's seasonality, but rather the presence of females in estrus.

Normal Breeding Behavior of Male Cats

The calling of estrous females when they are in season is definitely a well-known feature of their reproduction. This is how the males will locate them. When an adult male cat is in presence of an estrous female, the courtship phase will begin.

The male cat may exhibit a flehmen reaction by opening his mouth, slightly closing his eyes while sniffing, an action associated with reception of pheromones of the female by the male's vomeronasal organ. The flehmen reaction in the male is influenced by presence of testosterone in the male, as well as by fluid-borne chemical stimuli in urine and vaginal secretions of the female.

Neck grasp of the female

When the female accepts the male, this one will typically grasp her skin over the dorsal part of her neck with his teeth. This leads to immobilization of the female – a reflex that comes from kittenhood – which allows the male to perform coitus. This neck grasp is of great importance: if the male cannot perform it, breeding usually cannot occur.

It is therefore interesting to note that males that are suffering from dental disorders (like periodontal disease), joint issues or any other painful disorder will not be able to grasp the female's neck. That will impair breeding performances and even decrease libido (Malandain, 2006).

Breeding per se is very quick in cats. Pelvic thrusting by the male is followed by intromission and ejaculation which occurs in less than 20 s. The male then pulls away quickly to avoid being struck by the female in her post-coital reaction, which is an aggressive reaction towards the male that happens right after coitus.

Post-coital reaction & number of breedings

Visualizing this post-coital reaction is of great important from a clinical standpoint: it is indeed the sign that confirms penetration did occur. That is therefore an important behavioral sequence to visualize in terms of breeding management in catteries (Fontbonne *et al.*, 2007).

The number one cause of infertility in the feline species is indeed absence of breeding. Observing the breedings and confirming the post-coital reaction is therefore a mandatory prerequisite when dealing with infertility in this species.

As that reaction subsides, the male usually will mount and breed the female again. The number of breedings that can be observed varies a lot and basically depends on the individual male.

Since ovulation is generally induced by coitus in the feline species, it is interesting to note as well that one breeding only induces ovulation in 50% of the females (Fontbonne *et al.*, 2007). Not only should the post-coital reaction need to be observed to confirm that breeding indeed occurred, but it is also important to observe how many breedings occurred. That will be an important data to consider when dealing with infertility issues in a breeding cattery for instance.

In one study, sperm extra-gonadal reserves were exhausted after 4 days of daily ejaculation and the sperm numbers obtained thereafter were equivalent to the daily sperm output. Those results suggest that male cats can be used at stud three times weekly without showing a drop in the numbers of sperm per ejaculate (Sojka *et al.*, 1970).

Since the queen typically ovulates several oocytes, superfecundation can happen in cats and inside the same litter, kittens from different fathers can be found. While this might happen often in free-roaming cats, this is something cat breeders try to avoid for obvious reason: in a breeding cattery, an estrous female usually should only have access to a single male (Malandain, 2006).

Environmental conditions

We often hear that cats thrive on familiarity and routine. This is definitely true in feline reproduction as well. Copulation may not be completed if the male is not yet acclimated to his environment (a process that may take 1–2 months). That is the reason why in breeding catteries, the females are usually brought to the male, and not the contrary.

Also, with breeding cats, it is very often recommended to use an experienced and quiet female with a young male. If the female's post coital reaction is aggressive, a young male might associate breeding with potential danger and source of stress. It might then simply refuse to further breed (Malandain, 2006).

Mating behavior usually ceases following castration of the male cat, but it may persist for as long as several years following castration of the experienced male cat.

Semen Analysis and Collection in Male Cats

The Male Cat's Ejaculate

Production of a fully functional spermatozoa typically takes around 60 days in cats.

Volume

The volume of sperm produced per ejaculation in cats is small ranging typically from 0.01 to 0.7 mL.

This is definitely a limitation when it comes to semen evaluation in this species, and one of the reason why this type of fertility test is usually not performed in routine in veterinary clinics, but only in veterinary reference centers or research facilities.

Sperm motility

Mean progressive motilities of 60–90% have been reported as normal in this species.

Sperm count

A cat ejaculate contains in average 8–30 million sperm cells, different reports mentioning that there can be between 3 and 153 million sperm cells per ejaculate (Johnston *et al.*, 2001). This number is of great importance, especially when it comes to assisted reproductive techniques.

Performing an intravaginal artificial insemination is the easiest assisted reproductive technique in cats. However, to obtain 80% fertility rate with this technique, studies have shown that at least 80 million sperm cells should be deposited inside the vagina, which represents the equivalent of nearly 10 ejaculates (Tanaka *et al.*, 2000).

On the other hand, when performing intra-uterine insemination, the same 80% fertility rate could be obtained with only 8 million sperm cell (which represents a single ejaculate) (Tsutsui *et al.*, 2000).

Based on those results, it appears that intra-uterine insemination is the best option when considering assisted reproductive techniques in cats (Fontaine *et al.*, 2010).

Abnormal forms

Cats – especially pure-bred cats – are known to be prone to teratozoospermia, which means that there are lots of abnormal forms in the ejaculate. One study reported that the median percentage of normal spermatozoa was 44% (ranging from 1% to 91%) (Axner and Linde Forsberg, 2007).

This is something that is also well described in wild felids, especially in those species with low genetic diversity.

Retrograde ejaculation

The tom cat is reported to ejaculate from 15% to 90% (average 46.8%) of the ejaculate retrograde into the urinary bladder during ejaculation (Dooley *et al.*, 1984).

From a clinical standpoint, this is something definitely interesting. Collection of urine by cystocentesis from the tom following ejaculation with examination of the urine sediment for sperm is a useful procedure in small animal practice to determine whether the cat is producing sperm or not.

From a clinical standpoint again, this is a simple technique that most veterinarians can have access to. It is certainly not as accurate as a performing a full spermogram – during which motility, numeration and percentage of abnormal forms of the sperm are analyzed – , but as we are going to see in the next paragraph, there are definitely limitations in this regard in the feline species for sure.

Semen Collection

The least we can say is that it is not easy to perform semen collection in cats. Different techniques are however described.

Artificial vagina

Male cats can be trained to be collected with an artificial vagina. Training is accomplished by repeated gentle handling of the male cat in the presence of an estrous female. When cats are used to the procedure, an estrous female might not be needed anymore.

This technique is however difficult to reproduce outside of a controlled environment. As mentioned before, cats thrive on familiarity and routine... and that is definitely not what would happen if male cats were to be brought to a veterinary clinic for semen collection.

As interesting as it sounds, this technique is unfortunately not suitable to a busy veterinary clinic environment and it is a clear limitation to the development of fertility assessment in male cats – while in dogs, this is something that can be performed in routine in most veterinary clinics (Fontbonne *et al.*, 2007).

Electro-ejaculation

Collection via electro-ejaculation is often considered as the norm in felines.

The nervous pathways of ejaculation are stimulated via electric shots delivered through a rectal probe, leading to ejaculation. This technique is obviously much more invasive and in domestic cats require general anesthesia of the male (Platz and Seager, 1978).

It is to date the technique that allows for the collection of the best semen sample in the male cat.

While there is no doubt the technique allows for quick and efficient semen collection in male cats – a full electroejaculation protocol does not require more than 15 min – in recent years, more and more ethical concerns were raised regarding this type of collection.

Moreover, the anesthesia that is required is also a concern for many owners, and definitely limits the use of the technique in veterinary clinics.

Urethral catheterization (see Fig. 4)

This technique is based on the use of a special anesthetic drug, called alpha2-agonists.

Ejaculation is indeed an alpha2 agonist process and in other species like in stallions for instance the use of those drugs like xylazine can even lead to ejaculation (Parkinson, 2009).

In cats, the use of alpha2- agonists like medetomidine or dexmedetomidine will not lead to ejaculation per se, but will induce a passive flow of semen from the cauda of the epididymes to the urethra. By then placing a urinary catheter inside the male's urethra, it then becomes possible to collect the semen of the male cat (Zambelli and Cunto, 2006).

Fig. 4 Semen collection via urethral catheterization.

The technique is very simple to use but there are two main limitations:

1. It requires to use high doses of alpha2-agonists, which might increase the anesthesia risk;
2. Moreover the volumes of semen collected are nearly 10 times lower than what is collected when performing electroejaculation, which makes it very hard to manipulate then. Indeed with electroejaculation, secretions from the prostate and the bulbourethral glands are collected as well while when using this technique, we only get the spermatic fraction of the sperm which makes handling of the semen even more difficult.

Assisted Reproductive Techniques

As described above, semen collection in cats is definitely not something simple to perform.

Only certain specialized veterinary centers (universities or research centers) will typically perform these kind of procedures. Moreover, the small volumes of ejaculate that can be collected by the various techniques previously described is definitely a limitation to the development and use of assisted reproductive techniques like described in other mammalian species (Fontaine *et al.*, 2010).

Semen freezing and pregnancy following the use of it has been successfully reported in cats, however, because of the aforementioned difficulties, there is no commercial semen extender available to date.

Prevention of Fertility in Male Cats

It is not common to discuss how to evaluate or enhance semen quality in cats because of the limitations we just discussed. On the other hand however, neutering and prevention of fertility is a heavily discussed topic that is definitely worth mentioning in this article.

As we mentioned in the introduction, cat overpopulation is a problem in many parts of the world, including developed countries. While cat population control programs obviously need to focus on both the male and female aspects, we will focus here only on what is important to know about the male.

This is obviously something of interest for people involved in cat rescues and humane societies, as well as for any pet owner who considers neutering their pet.

Why Consider Neutering in Male Cats

Not all cats are intended to be bred. In order to better control the cat population, it is recommended that those animals that are not part of a breeding program should be neutered.

On top of population control measures, neutering also brings some strong health benefits to consider for pet owners.

Castration of the male cat will indeed lead to the decrease of many disturbing behaviors: aggressive behavior, mounting, roaming, and especially urine marking and urine odor.

Castration will eliminate sexual behavior immediately in most tom cats (except maybe the experienced ones as discussed earlier in this article) and will decrease the associated roaming.

Prepuberal castration is most effective in eliminating or preventing undesirable sexual behavior.

Inter-male aggression, which is normal in cats, subsides in 80%–90% of male cats castrated for this reason.

Prepuberal castration usually prevents urine spraying while male cats castrated in adulthood usually show postoperative decline in urine marking. A rapid decline in urine spraying occurred in 78% of 42 male cats castrated as adults, and another 9% showed gradual decline in spraying.

Side Effects of Castration

If there are obviously positive aspects to consider, castration – like all medical procedure however, also has its cons. Those are important to know as well.

Undesirable effects of feline castration include adhesion of the prepuce to the penis and delayed long bone physeal closure in cats castrated prior to 7 months of age, decreased nutritional caloric needs that may predispose to obesity.

When it comes to adhesion of the prepuce, in theory, these adhesions may be associated with buildup of debris and urine and predispose to local irritation, inflammation or ascending urinary tract infection. That being said, observations of such adverse sequelae has not been reported.

Physeal closure is delayed to 5–7 months in cats neutered at 7 weeks or 7 months of age; this results in long bone length that is about 10% longer than that of sexually intact littermate. Originally, this was thought to predispose cats to long bone fractures but studies have shown that in fact, it is not the case (Spain *et al.*, 2004).

Heat production, a measure of metabolic rate, was decreased an average of 28% in cats castrated at 7 weeks or 7 months when compared to intact toms (Root and Johnston, 1995). Therefore, neutered male cats require intake of 28% fewer calories than do sexually intact males in order to avoid signs of obesity.

This is definitely the biggest issue encountered after castration in male cats. Overweight/obesity in pets is indeed considered as a huge threat today in veterinary medicine, recent reports even indicate that 59% of cats seen in veterinary clinics are overweight or obese, and this condition is obviously associated with deleterious health effects.

That is why an important recommendation given to pet owners after castration in a male cat is to focus on their nutrition. Neutered cats should see their daily caloric intake monitored and decreased by around 30%.

Techniques for Neutering Cats

Today, the norm for neutering cats remains orchiectomy. Both testes are removed surgically. This is a fast procedure that is performed every day in most veterinary clinics (Fontbonne *et al.*, 2007).

Vasectomy can also be performed, but is usually only requested by cat breeders. A vasectomized tomcat can indeed be used as a teaser tom, which role is to induce ovulation in females and therefore increase their inter-estrus interval between litters.

Other noninvasive techniques exist and have been well documented recently.

While melatonin implants that are used more and more in female cats do not appear to fully prevent sperm production in males, there has been several publications done on the use of GnRH-agonists implants containing deslorelin in cats.

Those studies have shown that it is possible to induce reversible chemical sterilization using those implants in male cats for up to 2 years using a single implant. In this study, they indeed reported a mean duration of efficacy of 78.8 ± 12.9 weeks, ranging from 61.1 to 100.7 weeks (Goericke-Pesch *et al.*, 2014).

This can offer interesting alternative for breeders who do not want to neuter their cat but want to find a way to prevent the problems that comes with an entire male. This can also be an interesting alternative for cats that cannot undergo surgeries because of other health concerns (like cardiac or kidney disease for instance).

Pathology of Reproduction in Male Cats

Pathology of the Male Cat Genital Tract

Genital disorders in male cats are rather uncommon.

As mentioned earlier, cryptorchidism is the most common congenital defect of the urogenital system (Priester *et al.*, 1970). Feline cryptorchidism is more commonly unilateral than bilateral.

With the exception of a small number of prostatic adenocarcinomas, prostatic disease is almost unknown in cats, while it is extremely frequent in dogs for instance (Fontbonne *et al.*, 2007).

The Calico or Tortoise-Shell Males

Cats have 19 pairs of chromosomes and a normal male's chromosome formula will therefore be 38,XY (Parkinson, 2009).

Like in other mammals, abnormalities of sexual differentiation are described in cats such as abnormalities of chromosomal sex (such as 39, XXY trisomy or 38 XX/38 XY chimeras and mosaics); abnormalities of the gonadal sex (such as presence of ovotestes in true hermaphrodites) and abnormalities of phenotypic sex (such as male pseudohermaphrodite) (Johnston *et al.*, 2001).

Of particular interest in this species is what is observed in tortoise shell and calico males.

The male tortoise shell (black and orange – see Fig. 5) or calico (black orange and white – see Fig. 6) has been known since the early 1900s to be exceedingly uncommon and when found, to have a high incidence of sterility (Johnston *et al.*, 2001).

Orange and black coat colors are sex-limited traits in the cat. The orange coat color in this species is determined by a single gene located on the X chromosome. Therefore, black and orange may occur together in the female, but not in the male since they are carrying only one X chromosome.

Calico or tortoise-shell male cats are therefore three sex chromosomes: XXY.

While this is frequently associated with infertility, it is however interesting to note that some of those males have a normal fertility: one male tortoiseshell cat was reported to have sired 65 kittens in 2 years (Malandain, 2006).

Nutrition-Induced Testicular Degeneration

Testicular degeneration is typically associated with aging and lead to decrease sperm output and sperm quality, that will obviously ultimately impact fertility results (Parkinson, 2009).

In cats, testicular degeneration has also been associated with nutritional deficiencies.

Cats fed diets deficient in riboflavin, vitamin A or essential fatty acids (specifically linoleate, which the cat testis can convert to arachidonate) have been shown to undergo testicular degeneration and atrophy.

Male cats fed a riboflavin-deficient diet for 6 months showed complete aspermia, with decreased number of spermatids and an occasional increase in number of Sertoli cells (Gershoff *et al.*, 1959).

Kittens fed raw meat diet devoid of vitamin A from 12 weeks of age failed to show pubertal testicular development (Scott and Scott, 1964).

This is worth noticing because raw feeding is a growing trend in the cat breeder world.

Fig. 5 A tortoise-shell cat.

Fig. 6 A calico cat.

While the infectious diseases risks associated with this practice are now well described, it is worth adding that unbalanced diet – like what can be achieved when raw feeding the cats – can also impact fertility parameters as well.

Conclusion

Feline reproduction is definitely an interesting field of veterinary medicine.

Because of the current research projects in both animal population control and conservation biology, we now have a better understanding of the male cat reproductive function and a better idea of how to approach the different aspects of fertility in this field.

That provides us with clear elements to answer questions people might have on the male cat's reproductive function.

There are obviously still some limitations, especially in terms of assisted reproductive techniques. With the emphasis on conservation biology, there might however be more answers and alternatives in a near future.

Background

Phylogenetically, primates are a mammalian Order and that Order is still growing considerably with 234 species reported in 1996 and 505 species reported in 2016 including human (Rowe and Myers, 2016). Male reproductive functions can generally be described across four main categories A–D: (A) production and secretion of male reproductive hormones (e.g., testosterone) that are indispensable for achieving B–D but also influence a large variety of non-reproductive parameters in the male organism; (B) the production and maturation of male germ cells culminating in the production of spermatozoa (sperm) in the testis; (C) production of seminal fluid in the accessory male reproductive organs (e.g., epididymis/seminal vesicles/prostate/bulbourethral glands) and (D) transport of spermatozoa and seminal fluid into the female reproductive tract via a penis and ejaculation process. This article provides a comparative overview on these four categories across the Order Primates (men and male nonhuman primates (NHPs)).

The overall morphology of the male genital system of NHPs is similar to humans and other mammals. In adult primates, the testes are located in a scrotum outside the body. In all primates, the testes descend into the scrotum around birth (Martin, 2007). The scrotal location is necessary since the process of primate spermatogenesis – unlike in other mammals such as whales or elephants – requires temperatures below body temperature. However, testes can be retracted back into the external inguinal ring for protecting the organ or in species with distinct seasonality of reproduction. Anus, scrotum and penis are also denoted as external perineum. In some primates, this perineum can be intensely coloured and fulfils social and reproductive signalling function. For example, in the adult Patas monkey (*Erythrocebus patas*) the anal triangle is bright red and the scrotum is bright blue; and in the rhesus monkey (*Macaca mulatta*) the perineum is coloured intensely red during the active reproductive season.

Production and Secretion of Male Reproductive Hormones

Testicular functions, i.e., production of gametes and testosterone are controlled by endocrine factors derived from the brain across many species such as rodents, dogs and (nonhuman) primates (Ramaswamy and Weinbauer, 2015). In primates, the key hormones are testosterone, inhibin B and the gonadotropins Luteinizing hormone (LH), and Follicle-stimulating hormone (FSH). Hypothalamic gonadotropin releasing hormone (GnRH) controls pituitary LH and FSH synthesis, release and GnRH secretion is regulated by the neurohormone kisspeptin. The regulation of pituitary gonadotropin release is regulated by an ultradian cycle generated by a neuronal pulsatile network (Herbison, 2016). In the testis, Leydig cells produce testosterone under the influence of LH; Sertoli cells produce inhibin B under the influence of FSH, and both testosterone and inhibin B exert brain feedback regulation and a controlled interaction between hypothalamus, pituitary and testis (hypothalamus-pituitary-testis axis) is essential for intact male primate reproductive physiology. In peripheral blood testosterone is converted into estradiol which also exerts feedback effects on the secretion of GnRH, LH and FSH.

In primates, this axis is already active during embryonic development, but apart from short periods of activation after birth, remains suppressed during a prolonged period of reproductive quiescence until start of puberty (Plant, 2015), ultimately resulting in sexual maturity and fertility. In this context, primates are different from rodents lacking such prolonged period of reproductive hiatus. During pubertal onset, the hypothalamic pulse generator reactivates via kisspeptin, GnRH and gonadotropic hormones. The age at onset of puberty differs between males and females with females generally experiencing an earlier start, and the duration of the pubertal phase can be highly variable either between individuals of the same species (Luetjens and Weinbauer, 2012) or among closely related species such as chimpanzees (*Pan troglodytes*) and bonobos (*Pan paniscus*) (Behringer et al., 2014). In male primates, the reawakening of the GnRH pulse generator at the termination of the juvenile phase of development leads to re-initiation of gonadotropin release, reactivation of testicular testosterone secretion and the initiation of spermatogenesis relatively readily identified (Plant, 2015). Albeit under separate control, adrenal hormone secretion (adrenarche) starts in primates with chimpanzees and gorillas having similar adrenarche development to humans. During adrenarche the adrenal cortex secretes increased levels of androgens such as dehydroepiandrosterone and dehydroepiandrosterone sulfate, but without increased cortisol levels. Adrenarche means the development of a new zone in the adrenal cortex, the zona reticularis.

LH (indirectly via testosterone) and FSH directly stimulate Sertoli cells and spermatogenesis. In the immature primate testis, FSH potentiates the effect of LH on Leydig cell testosterone production. Beyond that, testosterone also exerts a variety of peripheral non-gametogenic effects such a sexual differentiation, testicular descent, perineum coloration, puberty-associated voice maturation, sexual behaviour and libido and on bone, muscle and lipid metabolism (Weinbauer et al., 2010). It is also assumed that testosterone may influence “male priming” during brain development and the maturation of the immune system. Recent investigations support direct production and activity of kisspeptin in testis and its involvement in the control of Leydig cells, germ cells progression and sperm function. The combined action of testosterone and FSH results in quantitatively normal production of germ cell numbers and sperm. In primates, either hormone alone can support the complete spermatogenic process but not the production of normal

germ cell numbers. Testicular concentrations of androgen levels can exceed peripheral blood concentrations up to 100-fold or beyond leading to the view that high local androgen concentrations are required for normal spermatogenesis. In primates, however, there is no direct correlation between intratesticular testosterone levels and the level of germ cell/sperm production. It is believed, that high local testicular androgen are rather required in order to provide sufficient peripheral testosterone levels and a pulsatile pattern of hormone concentrations.

Reproductive and developmental physiology has been described for number of primate species regularly used a research model and/or as preclinical model for human, comprising Old World and New World monkeys (Ramaswamy and Weinbauer, 2015; Tardif et al., 2012). Similar to other mammals, NHPs display significant annual differences in their reproductive activities depending on the habitat latitude. Species living in the northern hemisphere and exposed to distinct season with cold winters, exhibit seasonal reproductive patterns with sexual activity during autumn/winter and reproductive quiescence during spring/summer in order to ensure delivery of infants during appropriate climate conditions. Species with distinct reproductive seasonality are for example rhesus monkey (*Macaca mulatta*), Japanese macaque (*Macaca fuscata*) and bonnet monkey (*Macaca radiata*). Primates are short-day breeders with the reproductive activity being triggered by a shortened day length in autumn as opposed to long-day breeders such as sheep or rodents becoming sexually active during spring. During the out-of-season periods, reproductive hormone secretion and gonadal activity are at a complete halt triggered by the specific and day-length-related pattern of pineal melatonin secretion. Species living in the equatorial regions lacking significant seasons, typically are fertile throughout the entire year – e.g., long-tailed macaque (cynomolgus monkey, *Macaca fascicularis*), African NHP species and some New World monkey species such as marmoset (*Callithrix jacchus*). Long-tailed macaques may exhibit some adaption of reproductive activity based upon the onset of the raining season. Human are considered a non-seasonal species in term of reproductive activities.

In general, endocrine regulation of male reproductive functions is similar in anthropoid Old World monkeys (NHPs with African and Southeast-Asian habitats) and human with LH/androgen and FSH as the main factors. The LH/androgen setup, however, is fundamentally different in neotropical (New World) monkeys. This difference has initially been unravelled in the tuffed ear marmoset (*Callithrix jacchus*) but has been confirmed to other neotropical NHP species (Grzesik et al., 2015). These species lack LH but use chorionic gonadotropin (CG) instead of LH. Thus, CG is produced in the pituitary, stimulates testosterone production in the testicular Leydig cells and constitutes another primate gonadotropic hormone. LH and CG are heterodimeric glycoprotein hormones, consisting of a common alpha subunit and a specific beta subunit. It is believed that CG evolved by gene duplication of an ancient LH beta subunit gene approximately 40 million years ago. Specific to CG is a C-terminal peptide of 24 amino acids which was generated during evolution by the introduction of a point mutation shifting the open reading frame. The number of the CG beta gene amplifies with progressing evolution towards 7 CG beta gene copies (Troppmann et al., 2013). Along with this gene duplication, a mutation occurred in the sixth transmembrane domain of the LH receptor (LHR). While it was assumed that the function of CG in adult primates is confined to maintenance of pregnancy and early sexual differentiation, studies on the LH receptor revealed a dual action of LH and CG in primates. Thus, in primates two native LH receptor types exist. The wild-type LHR type 1 containing exon 10, which is present in Old World monkeys, great apes and the human lineage and the LHR type 2, lacking exon 10 in the New World monkey lineage. The LH/CG system independently evolved by geographical isolation and the ancestral functions of the LH/CG system remained in the neotropical taxa - double role of CG for pregnancy and male reproduction. Leydig cells with LHR type 2 produce testosterone in response to CG but not to LH. Interestingly patients lacking LHR exon 10 have been identified and are deficient in testosterone production. Based upon the knowledge about CG and LHR type 2, therapy with CG has been successfully introduced for some of these patients (Troppmann et al., 2013).

The key factors driving spermatogenesis are LH/androgen and FSH in Old World monkeys and human. Compared to rodents, spermatogenesis is particularly dependent on FSH vs androgens in Old World monkeys and human. Also, rodent and primate spermatogenesis respond quite differently to reproductive hormone withdrawal in terms of germ cell type-specific effects (Ramaswamy and Weinbauer, 2015). The primary spermatogenic lesion initially affects different germ cell types with spermatogonia in primates and spermatocytes/spermatids in rodents and the maximal spermatogenic suppression is more pronounced in NHPs compared to rat. It is less clear to what extent spermatogenesis in New World monkeys is dependent on established reproductive hormones. Administration of androgenic and gestagenic steroids – a well-established regimen for suppression of testicular functions and male contraception in macaques and men – produced comparable endocrine suppression (reduction of pituitary CG and testicular testosterone) in the marmoset but interestingly without effects on testicular function and fertility (Wistuba et al., 2013). Potentially, marmoset spermatogenesis is particularly dependent on FSH and/or rather independent of CG/testosterone. Alternatively, other unknown regulatory factors for male reproductive functions are active in the marmoset and possibly also in other neotropical primate species.

Production and Maturation of Male Germ Cells

Primate spermatogenesis encompasses germ cell development features common to other mammals but also primate-specific aspects. Mitotically active stem cells and spermatogonia provide the base of testicular gametogenesis followed by formation of meiotic spermatocytes and subsequently haploid spermatids which develop into testicular sperm via morphological and functional differentiation. Testicular sperm production depends on the number of spermatogonial multiplications, successful meiosis yielding four spermatids, differentiation of spermatids into testicular sperm and germ cell loss during the various development and division phases. In general primate spermatogenesis is comparatively efficient (Fig. 1). Primates differ from rodents with respect to the

Fig. 1 Micrographs of testicular histology from four different species showing typical organisation of the germinal epithelium. Roman numerals indicate stage of spermatogenesis. (a) Macaques (*Macaca fascicularis*): Predominantly single-stage tubules; (b) Baboon (*Mandrillus sphinx*): Mixture between single-stage and multi-stage tubules; (c) Marmoset (*Callithrix jacchus*): Multi-stage tubules; (d) Chimpanzee (*Pan troglodytes*): Multi-stage tubules.

testicular stem cell systems such that in primates fewer number/generations of stem cells are present. There are two separate cell types of undifferentiated spermatogonia: the A dark spermatogonia represent the mitotically inactive reserve stem cells (which only start to proliferate upon severe testicular damage), whereas the Apale spermatogonia represent a type of mitotically active progenitor cell. For example, the differentiating germ cells derived from the Apale population produce 128 sperm in the rhesus monkey and 16 sperm in man from each cell. By contrast, in rodents several generations of A-type spermatogonia exist and over 4000 sperm are being produced from a differentiating spermatogonium (Ramm *et al.*, 2014; Fig. 2). Other factors that determine testicular germ cell production are the conversion of spermatogonia into spermatocytes and the maturation spermatids. In this context, primate spermatogenesis is generally quite efficient (Fig. 3).

Fig. 2 Schematic depiction of male germ cell differentiation in the mouse, the macaque and man. Spermatogonial subtypes: As: Asingle; Apr: Apair; Aal: Aaligned; I: intermediate spermatogonium; B: B-spermatogonium. RS: round spermatid; ES: elongated spermatid. Note the very different number of spermatid produced per spermatogonial stem cell division in these three species. For this figure the spermatogonial renewal model proposed by Ramm, S.A., Schärer, L., Ehmecke, J., Wistuba, J., 2014. Sperm competition and the evolution of spermatogenesis. Molecular Human Reproduction 20, 1169–1179 was adopted.

The complex pattern of germ cell differentiation results in specific germ cell associations known as stages of spermatogenesis with each stage comprising spermatogonia, spermatocytes and spermatids during a specific development stage. The topography and number of stages is species-specific. For a stage-associated group of germ cells to pass through all stages requires approx. 10 days for most NHP species that have been studied, 14 days for the chimpanzee and 16 days for human (Amann, 2008; Luetjens *et al.*, 2005). For a differentiating spermatogonium to develop into testicular sperm, takes four spermatogenic cycles, i.e., 40 days for most NHP species, 56 days for chimpanzee and 64 days for human. A seminiferous tubule cross-section can either contain one spermatogenic stage (single-stage tubule) or several stages (multi-stage tubule) (Luetjens *et al.*, 2005). In men, great apes and neotropical monkeys multi-stages tubules prevail although New World monkeys separated from human and great ape line around 35 million years ago. In Old World monkeys (Afrika and Asia; Catarrhini) an intermediate type of organisation has been reported for baboon and mandrill. Single-stage tubules are predominantly found in macaques and vervet monkeys. The prosimians (Strepsirrhini) exhibit the lowest proportion of tubules with multi-stage. It appears that the single-stage organisation seems to represent a more ancestral stage which developed during evolution into an increasing number of stages per tubular cross section (Fig. 4). All germ cells within a given spermatogenic stage represent a single cell-derived clone. It is assumed that the origin of single-stage versus multi-stage tubules relates to the size of these clones: Small clones are associated with the multi-stage arrangement whereas large clones are observed in single-stage organisation. The comparison of efficiency rates among primates revealed similar values for all species indicating that the structural organisation is related to the yield of spermatozoa (Luetjens *et al.*, 2005) because they obviously need more space. The clonal size is determined by the number of Sertoli cells. A single Sertoli cell supports only a limited number of germ cells and the number of Sertoli cells determines the final testis size in mammals. The ratio between Sertoli cell and germ cells defines the Sertoli cell workload which obviously does not influence the spermatogenic efficiency, but is very likely to be a species-specific feature of the seminiferous epithelium (Luetjens *et al.*, 2005). The total number of spermatozoa produced is generally correlated only with the testis size, which is determined by the Sertoli cell number (Fig. 3).

Intrasexual selection occurs between males competing for access to females and vice versa. This access selection may not only mean to have physical intercourse. It could also be at a post-copulatory level – sperm from different males having to compete within the individual female tract for the oocytes leading to sperm competition from different males. Primates have many differing mating systems comprising single-male, multi-male, single-female and multi-female strategies.

As a result of different male mating systems the requirements for daily sperm production may have to differ reflected by the testis size. As an example, chimpanzees have bigger testes relative to their body weight than gorillas, orang-utans or humans (Ramm *et al.*, 2014). In some primates, testis size can be 1–5% of body weight (e.g., *Loris tardigradus*, *Saguinus oedipus*, *Microcebus murinus*) – for comparison relative testis size in men as around 0.06%. The testis/body weight correlates strongly with the mating system indicating that primates with lifelong partnership do not invest into testicular size. This finding supports the concept that species living in multi-male systems have often larger testes in relation to body weight than those with single-male systems (e.g., macaques and chimpanzees vs. marmosets, gorillas, orang utans and human). Sperm in the latter breeding systems supposedly do not have to compete for the oocytes against sperm from other males (Dixon and Anderson, 2004).

Fig. 3 Spermatogenic efficiency and meiosis indices for the rat, 13 primate species and man based upon flow cytometric data. The efficiency index is defined as the number of elongated cells divided by the total cell number. The meiosis index is defined as the number of haploid cells divided by the total cell number. n denotes the number of testes analysed. Data are means±SEM. The rat differs significantly from seven primate species (one-way ANOVA; P values encoded as af0.001, bf0.01, and cf0.05). Based upon Luetjens, C.M., Weinbauer, G.F., Wistuba, J., 2005. Primate spermatogenesis: New insights into comparative testicular organisation, spermatogenic efficiency and endocrine control. *Biological Reviews of the Cambridge Philosophical Society* 80, 475-488.

Fig. 4 Correlation between the percentage of multistage tubules and the average number of stages per tubular cross-section. The linear correlation elucidates that the species belonging to a certain systematic entity are grouped together. Overlapping is rare – the error bars are SD. a1 *Otolemur spec.*, a2 *Microcebus murinus*, b1 *Cebus apella*, b2 *Saimiri sciureus*, b3 *Saguinus oedipus*, b4 *Saguinus fuscicollis*, b5 *Callithrix jacchus*, c1 *Papio hamadryas*, c2 *Mandrillus sphinx*, c3 *Macaca nigra*, c4 *Macaca fascicularis*, c5 *Macaca tibetana*, c6 *Cercopithecus aethiops*, d1 *Pan paniscus*, d2 *Pan troglodytes*, d3 *Homo sapiens*, d4 *Pongo pygmaeus*. Organisation of the seminiferous epithelium in primates: Relationship to spermatogenic efficiency, phylogeny and mating system. *Biology of Reproduction* 69, 582–591.

Production of Seminal Fluid

Testicular spermatozoa are released from the testis into the epididymis via longitudinal contractions of the seminiferous tubules. There upon spermatozoa enter the vas (ductus) deferens that connects the epididymis to the urethra. The epididymis and a variety of glands along the vas deferens contribute to the composition of seminal fluid. The purpose of these contributions is to provide a suitable environment for spermatozoa for preserving their functional integrity (progressive motility and intact morphology) and to render seminal fluid as a transport medium for spermatozoa to enter the female reproductive tract.

Epididymis and Vas Deferens

This gland is composed of a singly and highly coiled duct and separated structurally and functionally into an initial segment that connects the organ to the rete testis followed by a caput, corpus and cauda segment. The vas deferens is a long, muscular tube carrying mature sperm from the epididymis to the urethra prior to ejaculation. The vas deferens joins the urethra just behind the bladder.

In some primate Genus the ejaculatory duct does not enter the prostate (e.g., Lorisidae, Tarsiidae). The primary function of the epididymis is maturation of sperm and storage of sperm. During transport along the epididymal duct, sperm mature functionally and gain forward progressive motility with sperm being only slightly motile in the caput region but having complete motility characteristics when leaving the cauda region. This is achieved by interaction of sperm with proteins and other factors provided by epididymal cells in a region-specific manner. The cauda region also serves for sperm storage and as sperm reservoir. Typically, the caudal fluid has low inorganic ions concentration but high concentrations of organic constituents, e.g., phosphatases, glycosidases, sialic acid, lactic acid, ascorbic acid, dehydrogenases, carnitine and glycerophosphocholine (Tardif et al., 2012). L-carnitine, glycerophosphocholine and neutral alpha-glucosidase are secreted from the epididymis and are also present in semen. Sperm maturation is defined by the ability to undergo capacitation and acrosome reaction. Macaques and marmosets display an acrosome maturation profile that is comparable to that in human and this functionality increases as sperm move from the caput to the cauda of the epididymis. Functional sperm maturation also comprises remodelling of sperm chromatin into a highly condensed form. It appears that this remodelling can occur independent of reproductive hormones.

Prostate/Seminal Vesicles/Bulbourethral Glands

The prostate surrounds the urethra, the tube that carries the ejaculate that is expelled from the body during orgasm. In macaques, prostate anatomy and zonation are roughly comparable to the human prostate whilst in other primate species the anterior part

found in humans maybe lacking. Single-lobed prostate has been described for the marmoset (*Callithrix jacchus*) and pigmy chimpanzee (*Pongo pygmaeus*). The prostate gland provides zinc, citric acid, prostate-specific antigen, acid phosphatase and acid alpha-glucosidase to the seminal fluid.

The paired seminal vesicles and the vas deferens join together to form the ejaculatory ducts, which empty into the urethra. Seminal vesicles produce fructose, prostaglandins, carnitine, glycerophosphocholine and seminogelin. The latter is a key factor for liquefaction of seminal fluid outside the male body. Bulbourethral glands are also known as Cowper glands, provide mucus proteins that lubricate the urethra and counteract the acidity of any urine leftover in the urethra.

Semen

Semen is composed of seminal fluid and sperm. In some primate species, e.g., rhesus monkey and cynomolgus monkey, the semen solidifies into a coagulum upon expulsion whilst in men semen is viscous initially but liquefies over time after ejaculation. Basic sperm morphology is similar across the Primate Order and sperm are composed of four regions: Head containing chromatin and the acrosome, neck with a centriole, midpiece containing mitochondria and tail. Species-specific differences relate to size of sperm, shape/size of sperm head and kinematic properties of sperm. Overall, sperm morphology and shape is extremely variable and sperm are considered among the most variable cell when comparing different species (quoted after [Ramm et al. \(2014\)](#)).

Transport of Spermatozoa

Transport of semen into the female reproductive tract is achieved via penile erection and ejaculation. Mammals typically use a penis to deposit the semen within the vagina/uterus (internal fertilization). The penis is typically cylinder-shaped and has several chambers inside made of erectile tissue (Corpus cavernosum penis). During sexual arousal these spaces fill with blood, which causes the penis to become rigid and erect, and enables the penis to penetrate the female reproductive tract during sexual intercourse. In general, penile size and penile morphology are species-specific and/or related to the mating system with corresponding vaginal/uterine morphological adaptations. The penis is responsible for expelling (ejaculating) sperm inside the female reproductive tract. In men, the urethra besides urine also carries semen, which is ejaculated during orgasm. Urine is prevented from entering the urethra while the penis is erect, which allows only semen to be ejaculated. In all Primates, the penis is pendulous but varies considerably with respect to size and details of surface structure e.g. penile spines and size/shape of the glans penis. In men, the penis is described as cavernous type as opposed to the fibro-elastic type (e.g., in cattle) in which the erectile tissue contains much connective tissue and during blood inflow the bent penis is being prolonged but grows little in diameter. In many NHPs an os penis (baculum) is present but such structure is lacking in men except for disease conditions and in some New World monkey species. The baculum is an ossification of part of the erectile tissue structures. The penis type in species with a baculum is therefore intermediate between cavernous and fibro-elastic type. Overall, there is great variation in baculum size and the presence of a baculum appears related to mating systems. The length of the baculum correlates with the duration of intromission over the course of primate evolution in extant primates and carnivores, and both polygamous and seasonal breeding systems predict significantly longer bacula in primates ([Brindle and Opie, 2016](#)). In men, a specific deletion in the androgen receptor gene eliminated a penile spine/vibrissae enhancer sequence ([McLean et al., 2011](#); [Reno et al., 2013](#)). Hence men maybe the only primate without baculum and sensory vibrissae and this appears to be the case also for extinct Homo species, e.g., Neandertal and Denisova. The presence of a baculum and vibrissae is regulated by androgenic hormones and this has been demonstrated experimentally in prosimian primates (*Galago* sp., [Reno et al. \(2013\)](#)).

Male ART in Animal Species

Robert V Knox and David J Miller, University of Illinois, Champaign-Urbana, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Artificial insemination (AI) Deposition of semen into the female reproductive tract by a method other than natural mating.

Artificial vagina (AV) A device that mimics the vagina and used to collect semen.

Assisted reproductive technology (ART) A group of technologies that promote reproduction.

Embryo transfer (ET) Transferring embryos from one female to another.

Intra cytoplasmic sperm injection (ICSI) Microinjection of a single sperm into an oocyte to achieve fertilization.

In vitro fertilization (IVF) Fertilization of oocytes in a laboratory culture dish.

Semen extender A medium into which semen is diluted in order to increase inseminate volume and sperm lifespan.

Super Ovulation (SOV) Hormone induced development of many ovarian follicles.

Introduction

Assisted reproductive technologies (ART) that manipulate the use of mammalian sperm in order to control fertility have been developed to the greatest extent for practical use in livestock species. The same technologies developed for use in livestock, were adapted for aiding human fertility control, and to help conserve wild and endangered animal species. Artificial insemination (AI) is perhaps one of the most widely used male ART that has impacted nearly all levels of animal production for controlled gene transfer to specific breeds of animals, herds, and even specific regions or countries around the world (Foote, 2002). The outcome from sire selection and distribution of the semen from these genetically superior sires has increased the rate and extent of genetic change with the most notable effects in milk, meat and fiber production. The ability to collect and preserve semen from superior breeding males has become the gateway technology for all other male ART. This article will describe several related technologies, such as in vitro fertilization (IVF), super ovulation (SOV), embryo transfer (ET), intra-cytoplasmic sperm injection (ICSI) and sperm sexing, as to their stage of development and use towards their potential to impact fertility in the future.

Artificial Insemination

Methods of Semen Collection

The earliest documented reports for semen collection for use in AI with domesticated mammalian species can be traced back to Russia in the 18th century using the dog. Subsequent efforts in the late 19th and early 20th century continued with dogs, rabbits, foxes, horses, cattle and sheep. Many of the significant advances in the development of AI occurred throughout the remainder of the 20th century in livestock species around the globe. Today, the majority of AI is performed to enhance the efficiency of food production in livestock. However, AI is also used in companion animal and exotic animal breeding, although to a much lesser extent.

For use with AI, semen collection is the initial step, and can be accomplished using an artificial vagina (AV), digital manipulation (the gloved hand technique), or with an electroejaculator. In the majority of species, semen collection is quick, with ejaculation lasting seconds and up to a minute. However, with pigs and dogs, ejaculation can take several minutes. The use of the AV and gloved hand technique rely on the male becoming sexually excited to achieve penile erection. This can be accomplished using an estrual female and allowing the male to naturally mate so as to help him learn to associate the collection area with sexual excitement and ejaculation. The male can be trained to mount a collection dummy or phantom that mimics the height and width of a female. Estrual females can also be used to collect semen, but may need to be restrained so the male can mount and semen can be collected using the AV or gloved hand. However, a male trained to a collection dummy is much more practical and efficient. Training the male to become excited in the collection pen, to mount the dummy and achieve an erection is accomplished by association. One male can be stimulated by watching another trained male mount the dummy while in an observation pen. The male can also be sexually stimulated by the smells and secretions of males previously in the pen and on the collection dummy.

Stallions, bulls, bucks, rams, boars, as well as the males of many other species such as cats and dogs, respond well to the use of the AV, while the digital or gloved hand technique is most commonly used for the boar and dog (Hopkins and Evans, 2003). The dimensions of the AV need to be suited to species length and width of the penis for collection. The AV must function to mimic the temperature, pressure and tactile stimulation of the vagina to induce ejaculation. One end of the AV is open for insertion of the penis, and the other end tapers into a collection tube. The AV is filled with water to the required temperature and pressure. Funnel shaped rubber liners and disposable plastic liners are used to attach the AV to the semen collection tube. The innermost disposable liner helps prevent disease transfer among males, and limits bacterial contamination of the ejaculate. For commercial swine semen

production, semi-automated semen collection systems have been developed and placed into large commercial boar studs. These machines are based on the dummy and AV collection system, but with automated pressure and collection that do not require the gloved hand digital pressure for the 7–10 min of ejaculation. Electroejaculation of semen is also effective in many animal species, with different sized devices appropriate for animals ranging in size from cats to cattle. Other species such as the horse and pig do not tolerate the electroejaculation procedure well and therefore it is seldom used. For performing the procedure, an electrical probe is inserted into the rectum and a technician applies a series of low level electrical pulses to stimulate erection and then ejaculation. This method does not use a collection dummy, but is often used in combination with an AV to collect semen under proper temperature and hygienic conditions.

Methods of Sperm Preservation

Efficient distribution and utilization of sperm from genetically superior sires is the key to improved animal breeding for performance and production efficiency. To accomplish this, dilution and preservation of sperm following ejaculation is essential for use with ART. Hundreds of millions to billions of sperm are ejaculated in small or large volumes of seminal plasma, specific to each species. Sperm are highly sensitive to changes in temperature and the chemical conditions while in liquid suspension. Since the viability of sperm declines over time in the undiluted state, efficient processing of the ejaculate is required. To preserve sperm fertility for storage, avoiding temperature fluctuation is critical at all stages. Rather than transient increases and decreases in temperature after collection, a gradual decline in temperature is desired until dilution in a thermally matched extender. The ejaculate contains highly concentrated sperm in seminal plasma and both must be diluted to avoid extensive sperm damage during processing and storage.

Evaluation of the ejaculate immediately following collection is an important step in successful sperm preservation. Ejaculates are evaluated for concentration and volume to determine total sperm numbers, while sub-samples are evaluated by qualitative or quantitative methods for determining sperm motility and extent of abnormalities. These and other assessments are used to quickly determine whether the ejaculate meets the minimum quality criteria for preservation. With quantitative ejaculate measures, the dilution rate can be adjusted for numbers of motile and normal sperm for efficient sire utilization. When the ejaculate meets the quality criteria, the semen is diluted to the proper concentration and volume for packaging.

Preservation of semen in frozen or liquid form involves packaging sperm into single doses for storage and for later use with AI or in vitro procedures. As a liquid, sperm are packaged into bottles, tubes or bags and refrigerated. When frozen, sperm are most often packaged into straws and stored in liquid nitrogen at -196°C . Preservation of sperm for storage as a liquid is most often used for boars and stallions using a 1 step dilution process and slow cooling to storage temperature of $5\text{--}18^{\circ}\text{C}$. Stallion ejaculates result in ~ 14 AI doses with 1 billion sperm/50 mL of diluent and boar ejaculates provide up to 30 AI doses with $\sim 2\text{--}3$ billion sperm/in 75 mL. Extended liquid semen can retain much of its fertility for 2–4 days before use. In cattle, semen is stored frozen with the ejaculate extended and allowed to slow cool to 5°C before dilution in the freezing solution. A bull ejaculate containing ~ 10 billion sperm can be extended to create 500 AI doses with 20 million sperm/0.5 mL straw. The semen that has been frozen can be stored in liquid nitrogen to retain its fertility for many years.

The semen diluents used for refrigerated sperm in liquid form vary considerably but generally are formulated to provide an energy source (glucose), a pH buffering agent, electrolytes (potassium and sodium chloride so that the diluent is iso-osmotic), and selected additional ingredients to enhance membrane stabilization, reduce oxidative damage, and prevent bacterial growth for different periods of time. Milk based extenders have been popular and widely used for sperm membrane stabilization. For storage in the frozen state, the diluents are similar but contain egg yolk in the cooling extender, and glycerol in the freezing solution. The egg yolk components provide protection for the sperm membrane while cooling, and the cryoprotectant serves to prevent ice crystal formation inside and outside the cell during freezing.

One other form of sperm processing, encapsulation, has been under investigation in dogs, cattle and swine for many years (Perteghella *et al.*, 2015). Suspensions of sperm are mixed to create alginate droplets, and mixed with ions to form a gel. The sperm remain viable in the droplet for days and when placed in-vivo or in-vitro in a physiological salt solution, the droplets slowly dissolve to release the sperm. There is limited information on the commercial use of this technology, but it holds great potential for application with advanced ART using sexed sperm and IVF.

Technologies for Artificial Insemination

The use of ART with intensive livestock production predominates in developed countries in Europe and North America where $\sim 80\%$ of the dairy cattle and 90% of the swine are bred using AI (Riesenbeck, 2011; Stevenson, 2014). While AI can be successful in other livestock species, it is used to a much lesser extent in horses, sheep, goats, deer, buffalo, dogs and cats (Morrell, 2011). In these species, limits to wider application arise due to uncertainty in genetic value and economic return, as well as reduced sperm fertility and difficulty in the technical aspects of AI. In cattle, frozen sperm is imported and exported from *bos taurus* and *bos indicus* dairy and beef bulls maintained in numerous semen collection centers around the world (Thibier and Wagner, 2002). However, AI in beef cattle is uncommon since much of the commercial production is extensive on open grazing lands and estrus detection or ovulation synchronization are not widespread practices (Foote, 2002).

For successful AI in many of the species described, deposition of semen into the uterine body by transcervical passage of a catheter is desired to achieve good fertility with low numbers of sperm in small volumes. Locating and passing the catheter

Table 1 Ejaculate parameters of males and most common methods used in artificial insemination programs

Male (species)	Ejaculate				Artificial Insemination				
	Collection	Aids	Volume (mL)	Sperm ($\times 10^9$)	Sperm/AI dose	Storage form	Insemination	Species use	Inseminations/Female
Bull (<i>Bos taurus</i>)	AV/EEJ	Phantom/ Female	6	7	$20 \times 10^6/0.5$ mL	Frozen	Uterus	80%	AI once in mid estrus
Boar (pig)	DM	Phantom/ Female	250	60	$2.5 \times 10^9/75$ mL	Chilled	Cervix/ Uterus	90%	AI on Days 1 and 2 of estrus
Stallion (horse)	AV/EEJ	Phantom/ Female	70	9	$500 \times 10^8/75$ mL	Chilled	Uterus	Low	1 AI every 48 h during estrus
Ram (sheep)	AV/EEJ	Female	1	3	$200 \times 10^6/0.5$ mL	Chilled/ Frozen	Uterus	Low	1 AI near end of estrus
Buck (goat)	AV/EEJ	Female	1	2	$200 \times 10^6/0.5$ mL	Chilled/ Frozen	Uterus	Low	1 AI near end of estrus
Buck (rabbit)	AV	Female	0.8	0.4	$5 \times 10^7/0.5$ mL	Chilled	Vagina	Low	1 AI after induced ovulation
Dog	DM/AV	Female	10	2	$200 \times 10^6/5$ mL	Fresh/Chilled	Vagina	Low	AI on Days 2 and 4 of estrus
Tom (cat)	AV/EEJ	Female	0.06	0.1	$20 \times 10^6/0.2$ mL	Fresh/Chilled	Vagina	Low	1 AI after induced ovulation

Abbreviations: AV, artificial vagina; EEJ, electroejaculator; DM, digital method (gloved hand).

through the cervix may require manipulation through the rectal wall in cattle and horses, or by locating the opening using a speculum and laparoscope such as with small ruminants. Other species such as the pig are most often inseminated intracervically with high fertility while the cat is most often inseminated vaginally due to the structure of the cervix. The AI conditions used in various species are shown in **Table 1**.

Superovulation, Embryo Collection and Transfer

Being able to collect embryos from valuable donors and transfer them to surrogates that carry them through gestation has allowed females to produce many more embryos and offspring than they would if they gestated. Some cows have produced over 200 embryos in their lifetime. Superovulation (SOV) and embryo transfer (ET) are most commonly used in cattle. Although ET was performed successfully as a surgical procedure in rabbits over 100 years ago, the current non-surgical techniques used for cattle were not developed until the 1970s and 1980s (Kuzan and Seidel, 1986). Today, ET is commonly used in cattle reproduction. The first step in embryo production is to inject donor females in diestrus with FSH. These injections rescue ovarian follicles that would otherwise undergo atresia, resulting in super-stimulation of follicle development. Following an injection of prostaglandin $F_{2\alpha}$ to induce luteolysis, multiple follicles develop and ovulate following estrus. Cows are usually inseminated once based on signs of estrus. About one week after AI, each uterine horn is flushed with medium to collect embryos. The donor embryos can be transferred to the uterine horn ipsilateral to the corpus luteum in a recipient female that is in the same stage of the estrous cycle as the embryo donor. Alternately, the embryos may be cryopreserved and transferred later after thawing. The ability to cryopreserve embryos allows owners of animals with high genetic merit to ship embryos around the world at a significant cost savings compared with shipping live animals. In cattle, the economic value of producing more offspring with high genetic merit makes the ET procedure profitable. However, in other species, ET is seldom used due to the uncertainty in the economic value and absence of practical methodology.

In addition to increasing the number of offspring produced by a single female, another advantage of ET is that the generation interval can be reduced to increase the rate of genetic selection by flushing embryos from females soon after they have reached puberty. In this scheme, the surrogates could deliver offspring from the transferred embryos before the embryo donor carries an embryo to term. Indeed, some very high genetic merit cows spend more of their lifetimes producing embryos than carrying them.

In-Vitro Fertilization

In vitro fertilization (IVF) in most mammals, with the exception of humans, is primarily a research procedure. It has been used to develop a clearer understanding of the principles of fertilization and what factors influence its outcome. In cattle, IVF is becoming a more common commercial practice to produce embryos from cows that do not respond well to SOV. In addition, it can be used to produce embryos of a specific gender using sex chromosome-sorted sperm. Despite these opportunities, IVF is still not commonly performed. In other species, such as the horse, IVF yields poor fertilization rates for reasons that remain unclear.

Successful IVF requires that both gametes undergo final maturation. Oocytes can be collected from animals in an abattoir or from live animals by aspiration of oocytes via laparotomy guided by ultrasound. Oocytes can even be collected from young females prior to puberty. Oocyte maturation is usually accomplished by in vitro culture in medium supplemented with hormones such

as FSH and LH or the growth factor EGF. Fully mature oocytes have an expanded cumulus oophorus, have resumed meiotic maturation and progressed to metaphase II, and have developed the ability to decondense the sperm nucleus (Fig. 1).

Sperm must also complete a final maturation, known as capacitation. The requirements for capacitation vary to some degree between species. For example, mouse and porcine sperm are usually capacitated by incubation in a simple salt solution including calcium with bicarbonate and albumin. In contrast, bovine sperm capacitate most effectively when the glycosaminoglycan heparin is added to the medium and glucose is absent (Parrish, 2014). The reasons for the differences between species are not clear. Regardless of medium composition, a certain minimum incubation time is necessary for capacitation. The duration of capacitation also varies between species. Mouse sperm capacitate in an hour whereas it takes 4–5 h for bovine sperm to complete capacitation. The next step in IVF is to add capacitated sperm to mature oocytes to allow fertilization. Zygotes are then transferred to fresh medium and allowed to develop to the morula or blastocyst stage, a stage appropriate for transfer to the uterus of recipient females or for cryopreservation (Fig. 1).

Separating Sperm by Sex Chromosomes

The sex chromosome of the fertilizing sperm determines the sex of the offspring. The ability to separate live sperm based on the presence of an X or Y chromosome to produce nearly all males or females can be accomplished based on the difference in total DNA. The X chromosome is larger than the Y chromosome, yielding a difference in total DNA of about 3–4% in several species whose sperm have been sorted, including cattle, swine and sheep (Gamer, 2006). Following staining with a fluorescent DNA-binding dye, this difference can be used to identify and separate X and Y sperm using a flow cytometer. The process is limited by the speed at which sperm can be sorted, currently about 20 million per hour. But despite this obstacle, bovine sex-sorted semen has been available commercially in the cattle industry for about 10 years. It is used mostly by dairy farmers because of the higher value of female offspring compared to male offspring. The same process can be applied to sperm from other agricultural species but there are a couple of limitations. In swine, conventional artificial insemination requires billions of sperm, compared to the 2–4 million sex-sorted cattle sperm that are typically inseminated. And the difference in the value of females and males in most other agricultural animals is much lower, providing less profit incentive at the production level, to sex-sort sperm.

Intracytoplasmic Sperm Injection

Typically, successful IVF requires thousands of sperm in the droplet volume with oocytes to obtain satisfactory fertilization results whereas AI requires millions to billions more. In contrast, using a micromanipulator, one can select a single sperm and inject it into the oocyte cytoplasm to obtain fertilized eggs using ICSI (Galli *et al.*, 2014). Oocytes may be aspirated from ovaries at slaughter or by ultrasound guided ovum pickup via standing laparotomy. If oocytes were from small follicles, they must be matured in vitro. If they were aspirated from large follicles, they will require less time for maturation after collection. After maturation, the cumulus cells will be removed using hyaluronidase. Maturation can be confirmed by assessing extrusion of the first polar body. Fresh or cryopreserved sperm are usually used for ICSI but even freeze-dried sperm can be used. Using a micromanipulator, a large diameter holding pipette (120–140 μm outer diameter) is used to hold the oocyte while another small diameter pipette (7–8 μm outer diameter) is used to aspirate a sperm following immobilization. Usually a hole is made in the zona pellucida using a Piezo drill so that the sperm injection pipette can be passed through the zona to reach the oocyte plasma membrane. The injection pipette is then advanced through the oocyte plasma membrane and the sperm is ejected into the oocyte cytoplasm without aspirating any

Fig. 1 Microscopic images of (a) unfertilized eggs; (b) cumulus-free egg and sperm for in-vitro fertilization; (c) fertilized egg with male and female pronuclei; (d) unfertilized eggs and 2–4 cell embryos; (e) 8 cell embryos; (f) blastocyst stage embryos ready for transfer into recipients. cytoplasm. The resulting zygotes are cultured in droplets to assess cleavage and development and then either transferred or cryopreserved. A major advantage of ICSI is that few sperm are needed. Abnormal sperm and even epididymal or testicular sperm can be used for ICSI or sperm that have been freeze-dried and are dead. Although this technique is used routinely in humans, success rates in some species such as cattle are much lower. Yet in horses, ICSI is used more commonly because of the very poor fertilization and development rates with IVF (Rader *et al.*, 2016). One interesting application of ICSI is to inject sperm coated with vector DNA to produce transgenic animals.

Sperm Selection Techniques

Although millions to billions of sperm are deposited in the female reproductive tract with natural mating or when using AI, only a very small fraction of the sperm are found in the oviduct, the site of fertilization. The genital tract removes the majority of sperm by retrograde flow, phagocytosis or retention in the lower tract. The mechanisms by which sperm are selected to advance to the oviduct are unclear. In the laboratory, there are several techniques employed to select elite sperm and improve fertility with ART but it is not clear how well any mimic the natural selection that occurs in the genital tract or even if this natural selection actually selects the very elite sperm (Sakkas *et al.*, 2015). For most ART procedures, one needs only a small number of cells, so the goal is to select the sperm that will give the greatest success. Only a couple of techniques are used routinely to select sperm for ART procedures, such as IVF. The sperm swim-up technique is a sperm motility challenge. To be selected, sperm must swim from the semen layer into a layer of medium overlaid above the semen. Motile sperm are selected but the yield is low. Another common technique is to separate sperm based on density by centrifugation through Percoll or other coated silica. The density gradients that are used may have continuous or discontinuous densities. The yield of sperm after density gradient centrifugation is higher than swim-up but correspondingly there may be less stringent selection. The procedures for swim-up and Percoll density gradient centrifugation for sperm selection are very similar across species.

There are several other sperm selection techniques that are not used frequently for animals, such as hyaluronic acid binding, DNA/chromatin integrity separation, and removal of apoptotic cells by Annexin V binding (Rappa *et al.*, 2016; Sakkas *et al.*, 2015). Annexin V binds to sperm that have phosphatidylserine exposed on the sperm exterior, indicating that membrane integrity is compromised. In normal non-capacitated sperm, phosphatidylserine is located on the inner leaflet of the sperm plasma membrane and inaccessible to Annexin V. Coupling these selection approaches with flow cytometry to separate high and low fertility sperm can be done on a small scale appropriate for most ART procedures.

In addition to flow cytometry, physical separation of sperm that bind Annexin V has also been accomplished using magnetic activated cell sorting (MACS). Annexin V coupled to colloidal supramagnetic beads binds dead and apoptotic sperm and when placed into a magnetic field, bound sperm can be removed. MACS separation can even be combined with density gradient centrifugation for even greater selection enhancement. Microfluidic devices have been developed to sort sperm in small channels based upon motility and morphology. The flow of medium through these channels is used to flush out immotile sperm. These procedures have been limited mostly to animals in a research setting and the procedures have not been standardized for routine use in clinics or in sperm selection for genetics company sires. Furthermore, these selection procedures only yield relatively small numbers of sperm; too few for routine use with AI.

The fertility of live normal sperm in a semen sample with a large number of dead cells could be compensated by simply inseminating more sperm, which is why the number of dead cells is considered a compensable trait. But it is possible that the reactive oxygen species produced by a large number of dead or abnormal sperm may compromise the fertility of the normal sperm. Timely removal of the damaged sperm prior to AI could improve fertility. There is research interest in the use of nanoparticles for removing defective sperm in scaled-up systems that would yield an adequate number of sperm for AI doses. Further, nanoparticles conjugated with lectins or Annexin V may remove acrosome-reacted or apoptotic sperm from large semen volumes. Using nanoparticle conjugates to remove poor sperm might improve the fertility of males that produce sperm that do not survive cryopreservation or are affected significantly by thermal stress.

Strategies to Interfere With the Function of the Hypothalamo-Pituitary-Testicular Axis in Males

The purpose of contraception in males is to prevent endocrine (production of testosterone that supports sperm production and generates sexual behavior) and exocrine (sperm production) production by the testis.

As sperm production is under the control of the gonadotropins, luteinizing hormone (LH) and follicle stimulating hormone (FSH), as well as testosterone (itself LH dependent), efficient contraceptive strategies have attempted to act at the top of the hypothalamo-pituitary axis to prevent synthesis and release of LH and FSH. When FSH and LH concentrations reach low levels, testosterone production in the testes is significantly reduced. The low gonadotropin and testosterone concentrations do not support sperm production, and when testosterone concentrations are low, male sexual behavior is inhibited. Therefore three main approaches to suppress gonadotropins have been tested: (1) sustained administration of GnRH agonists (e.g., deslorelin or azagly nafarelin) that trigger down regulation of the GnRH receptors and desensitization of pituitary gonadotropes, (2) active immunization against GnRH resulting in antibody binding of GnRH in portal blood before it reaches the pituitary and (3) the use of GnRH antagonists that bind to the GnRH receptors (therefore preventing binding of native GnRH) blocking their activation and therefore suppressing LH, FSH and testosterone.

The first two options, for which extensive data are available, will be discussed throughout this review, with emphasis being placed on products that have been achieved regulatory approval, and therefore have extensive safety and efficacy data available (Fig. 1).

In addition, in recent years, a strategy whereby sterilization is achieved by intra-testicular injections of compounds (Kutzler, 2015) that destroy the seminiferous tubules has been proposed and shown to work in pets and cattle. This option will be briefly discussed in the last section of this review.

Why Suppress Male Reproductive Activity: Which Needs in Specific Species?

There are several reasons (summarized in Table 1) for asking for a contraceptive strategy for males. The most obvious indication for requesting contraception (if the animals are not simply surgically castrated) is stopping the males from mating and producing unwanted progeny. This indication applies to all companion animal species (particularly dogs and cats) and is usually life-long. For this sub-population, the main goal is high efficacy and the global lack of treatment associated safety issues. In animals where surgical castration is contra-indicated because the animal may be used for breeding some time in the future, or because anesthesia may be risky, a non-surgical alternative may be preferred.

A similar need for lifelong contraceptive/sterilant strategies is triggered by the large population of stray dogs and cats living in some highly populated environments where their interactions with the human population may not be safe, where they may

Fig. 1 The 3 main strategies used for achieving contraception in males.

Table 1 Possible reasons for requesting a contraceptive treatment in males for a range of species and associated technical solutions

<i>Indication</i>	<i>Species</i>	<i>Main needs</i>	<i>Treatment regime</i>	<i>Preferred treatment</i>
Fertility control	Pets (cats & dogs)	High and long efficacy, very good safety	Yearly implant injection by vet	GnRH implant
Behavioural control	Pets (cats, dogs and stallions)	Obvious long lasting efficacy & very good safety	Implant placement by vet & owner's monitoring	GnRH implant
Testosterone dependent pathologies	Pets (cats, dogs and stallions)	Very high efficacy	Repeated treatments and monitoring of effects by vet	GnRH implant or GnRH vaccine
Population control	Stray dogs and cats & wild deer, boars	Single, low cost treatment, easy to administer	Handling and monitoring by field workers	One shot GnRH vaccine or testicular sterilant
Zootechnical use	Boars & bulls	Failure proof unexpensive treatment, OK for consumers	Administration of vaccine (primary and booster) by farmers	GnRH vaccine

interfere with the local biodiversity and where they may carry diseases such as rabies. This need also applies to wildlife species living in zoos or reserves where the amount of land available only allows carrying a specific population size. For this sub-population, the main constraints are a long lasting efficacy, easy implementation and cost effective treatments.

Short/medium term contraception may also be useful in some farm animal species (swine, cattle) if surgical castration is perceived as unethical owing to the pain and discomfort generated by some surgical procedures.

In farm animals, testosterone production improves feed efficiency (i.e., the conversion ratio of food into muscle), but may have negative effects on meat quality in some species. Meat of boars (at least a fraction of them, ranging between 5% and 30% according to their genetics) slaughtered after puberty, displays “boar taint” an off flavor where the meat has a urine and faeces odor when cooked. This feature is obviously not wanted by consumers, and can be prevented by surgical castration. However, the same consumers may consider unethical the pain induced by piglet castration. Pharmaceutical suppression of testicular androgen production is therefore important in post-pubertal boars presented for slaughter. Furthermore, in all intact animals used for meat production, meat is less tender and leaner (i.e., less tasty and juicy). This is why, in many beef production systems worldwide, steers are treated with steroid implants during the fattening phase. A short term contraceptive treatment if available to the producers, could offer a combination of high feed efficiency during most of the growth phase of the animal, followed by a “no testosterone” phase caused by the contraceptive treatment (during the 2–4 weeks before slaughter) to ensure good meat quality. For this sub-population, the main constraint is consumer acceptance as well as a cost effective treatment.

Finally, treatments whereby production of testicular steroids is prevented may be significant treatment aids to stop testosterone dependent diseases (benign prostatic hyperplasia in dogs, equine arteritis virus infection in stallions). For this (small) sub-population, the main goal of such treatments is high efficacy and an acceptable risk/benefit ratio owing to acceptable adverse effects of treatment.

The Available Solution for Contraception in Male Dogs: GnRH Implants

There are several reasons why owners may seek contraception for their male dog. They include reluctance to get the dog surgically castrated for ethical (animal welfare) or anesthetic risk reasons, or the desire to breed this dog in the future. In addition, some owners may want to take time before making the decision to surgically castrate their pet and therefore need a temporary contraception before making a final decision. The GnRH agonist releasing implants act by causing desensitization of the pituitary, therefore reducing gonadotropin support to testicular function (endocrine and exocrine) during the time frame during which the GnRH agonist is released. Towards the end of the release period, testicular function and fertility may resume or a new treatment may be applied. Two GnRH agonist implants have been developed for this purpose. The first one (Suprelorin, commercially available in Europe and Oceania) uses deslorelin as GnRH agonist (with 4.7 and 9.4 mg of deslorelin to achieve 6 or 12 months of fertility suppression, respectively) in a biodegradable controlled release matrix. The second one (Gonazon, approved by EU regulatory authorities but not commercially available) uses azagly nafarelin, a different GnRH agonist, in a solid silicone based matrix.

Mode of Action

Following a brief (1–2 weeks) flare up period during which gonadotropin concentrations are increased, irrespective of the GnRH agonist used, gonadotropin concentrations drop to basal levels owing to the combined effects of down regulation of pituitary GnRH

receptors together with a drop in LH/FSH gene expression (review: Goericke Pesch (2017)). Consequently, testosterone concentrations also drop to undetectable values, 6–43 days following insertion of a deslorelin implant (Trigg *et al.*, 2006) and 17 ± 8 days following insertion of an azagly nafarelin implant (Ludwig *et al.*, 2009). The underlying mechanism causing azoospermia or aspermia is an arrest of spermatogenesis at the spermatogonia/spermatocyte level (Goericke Pesch, 2017).

Safety and Efficacy

The duration of fertility suppression of the deslorelin implants is variable, and although the minimum duration of efficacy has been shown to reach 180 days (4.7 mg implant) and 400 days (9.4 mg implant) (Trigg *et al.*, 2006), the median duration of efficacy reach 300–400 days (large and small dogs respectively), when using the 4.7 mg implant (Trigg *et al.*, 2006). The lack of endocrine support to the testis (basal LH and testosterone concentrations) triggers a drop in sperm quality (reduced semen volume, massive increase in tail abnormalities of the spermatozoa produced), together with a strong decrease in libido. By 30–35 days post implantation, semen production has ceased and libido is absent (Trigg *et al.*, 2006). Such a treatment appears to be very safe, as there was no inflammation or pain detected at the implantation site. In addition, repeated treatment of the same male dogs proved to be well tolerated, therefore offering an option to generate permanent efficacy (Trigg *et al.*, 2006). Duration of efficacy of the azagly nafarelin containing implant (Gonazon) ranged between 223 and over 365 days (Ludwig *et al.*, 2009).

Reversibility

All endocrine and exocrine effects of treatment were shown to be fully reversible following implant removal (Gonazon) or exhaustion of the deslorelin load (Suprelorin). Recrudescence of testicular steroidogenesis is rapid, as testosterone concentrations are back to pre-treatment values at 7–8 weeks post implant removal (Ludwig *et al.*, 2009). Testicular size and normal semen quality were back to normal values around 9 weeks after a 4.7 mg deslorelin implant has emptied (Trigg *et al.*, 2006) and 16–30 weeks after Gonazon removal (Ludwig *et al.*, 2009). As the dynamics of the post removal recovery process are very variable, no specific claim of reversibility time is made on the approved product.

The Available Solutions for Contraception in Tom Cats (GnRH Implants)

If a male cat is an indoor pet, an owner may request contraception to control behavioural conditions such as vocalization and urine marking. Having the option to breed once from their pet cat may sometimes be a wish. In such cases, treatment of the cat with a GnRH agonist containing implant (such as Suprelorin or Gonazon), may provide a suitable solution to such requests. For male cats living outdoors, the reasons for requesting contraception are different and relate to the owner's perception of the responsibility to keep feral cat populations under control and avoid fights and wounds generated by fights between breeding tom cats. Suprelorin in cats is not approved and therefore any use would be 'off label'.

Mode of Action

The mode of action of GnRH agonist releasing implants is essentially similar in dogs and cats. Hence the reader is referred to the dog GnRH implant section for information.

Safety and Efficacy

As in dogs, there is a brief flare up period following GnRH agonist implant insertion. Following application of a 4.7 mg deslorelin implant, the time to suppression of fertility ranged between 3 and 11 weeks (Goericke Pesch *et al.*, 2011). The reasons underlying this high variability are not fully understood. Lowest semen quality was usually reached around two months after treatment. However, a similar large variation in sperm features was also detected with some tom cats having no motile sperm and very low total sperm counts, while others display larger numbers of total and motile spermatozoa in their ejaculates. When testicles of treated tom cats were examined by histology, a large between male variability was again detected with spermatogenesis being arrested at variable levels including elongated spermatids. Overall, the mean duration of efficacy of a 4.7 mg deslorelin implant was 551 ± 90 days, again displaying a large individual variability 432–705 days) (Goericke Pesch *et al.*, 2011).

Reversibility

Testosterone concentrations start to recover within one month after removal of a deslorelin implant, as does testicular size. Total sperm counts are back to normal values 3 months post removal (Novotny *et al.*, 2012). After removal of an azagly-nafarelin implant, normal fertility was regained and following mating, litter size was not different from that of untreated males (Goericke Pesch *et al.*, 2011).

The Available Non-Surgical Solutions for Interfering With Gonadal Function in Male Farm Animals (GnRH Vaccines)

Castration of young male farm animals (swine, cattle) is common as (1) it helps management of male animals, particularly when they are co-mingled with females, (2) it improves meat quality (by promoting marbling) and (3) it prevents meat from male pigs to display boar taint, a off-flavor of meat. However these benefits are at the expense of the improved feed efficiency (efficiency of conversion of feedstuffs into meat proteins) that is better in intact males. This is why several groups have attempted to develop GnRH vaccines that would allow high feed efficiency, while also promoting the benefits listed above.

The purpose of this strategy is production based (alternative to castration to optimize animal welfare and to optimize protein and fat accretion in meat).

Mode of Action and Purpose

The vaccination schedule includes a primary injection and a booster injection, usually several weeks later. GnRH antibody titers rise following the booster injection, therefore preventing LH release hence blocking testicular function. More specifically, Leydig cells when deprived from LH support stop producing the steroids responsible of lean meat (testosterone) and boar taint (androstenone).

Safety and Efficacy

Scientists at CSL in Australia developed a GnRH vaccination strategy that proved very efficient in swine (Improvac vaccine: [Dunshea et al. \(2001\)](#)) as well as in cattle (Bopriva vaccine: [Amatayakul-Chantler et al., 2012](#)). In swine ([Dunshea et al., 2001](#)), this vaccination has multiple benefits: first, male piglets do not need to be castrated in the days following birth, a procedure raising ethical issues because it is commonly done without anesthesia. Second, in the time interval between the primary injection and the booster, boars display the high feed efficiency typical of intact males, as the primary immunization does not cause high levels of GnRH antibodies and testosterone is not suppressed. Third, following a booster injection, testicular function of GnRH immunized boars is significantly reduced, stopping the production of the testicular steroids (androstenone) responsible of boar taint. Finally, GnRH immunized boars, when achieving high GnRH titers, have an increased ability to accumulate fat in meat (marbling) generating more tender and more tasty meat. Boars need to be slaughtered no earlier than 4 weeks and no later than 8 weeks after the booster injection.

Similar results have been reported in bulls, although meat of intact bulls does not display any detrimental taste (as in boars) and is only less tender and less tasty ([Amatayakul-Chantler et al., 2012](#)). In both species, no safety issues secondary to vaccination have been observed. Local reactions at the injection site are minimal and risks for the consumers are minimized by the long time lag between the booster injection and slaughter.

The Available Contraceptive Solutions for Controlling Populations of Wildlife (Single Injection GnRH Vaccine)

There is a need for population control in wild animals where keeping a suitable balance between animal numbers, such as deer or wild horses, and the feeding capacity of their environment and minimizing issues with agricultural damage, negative conservation impacts and risks for public safety are needed. The target strategy for this purpose is a single injection treatment given when the animals are captured in traps, or given by darting that induces very long term infertility. Another important constraint for this use is that treatments must be cost effective.

Mode of Action and Purpose

The joint need for a cost effective single injection treatment ensuring long term efficacy suggested that a potent GnRH vaccine might be the best candidate. Gonacon, a GnRH vaccine developed by the National Wildlife Research Center (NWRC) of the United States Department of Agriculture (USDA) which combines GnRH conjugated to a carrier protein (keyhole limpet hemocyanin or “blue protein”, another marine mollusk hemocyanin) in a strong adjuvant (AdjuVac) containing *Mycobacterium avium* proved to deliver consistent results in several populations of wild animals and was approved by the US Environmental Protection Agency (EPA) as an option to control populations of deer and wild horses.

Safety and Efficacy

While most of the data documenting success of this approach have been generated in females, which are the obvious sex to be targeted for population control, there are some lines of evidence showing efficacy in males as well. For example, [Gionfriddo et al. \(2012\)](#) demonstrated that Gonacon vaccinated male deer displayed a titer dependent suppression of gonadal function with reduced testicular sizes and antler development.

The Available Non Hormonal Solutions for Controlling Populations of Stray Tom Cats and Male Dogs (Intra-Testicular Injection of Chemical Solutions)

The aim of this approach is population control. In some cities and environmental niches, population of stray dogs and cats may proliferate if food supply is available and if there are no predators. The idea of inducing long term sterility by intra-testicular compounds triggering prolonged azoospermia (or teratospermia) has been around for several decades.

As a cost effective and not technically difficult to achieve and potentially generating permanent contraception, such an approach may be attractive for controlling the populations of stray dogs and tom cats.

There are two solutions that have been evaluated for intra-testicular sterilants in male animals, calcium chloride, and zinc gluconate (also known as Neutersol, Esterisol and Zeuterin).

Mode of Action

The intratesticular injection of these solutions targets the seminiferous tubules which are selectively destroyed. The Leydig cell population may be affected to some extent, but testosterone concentrations, although somewhat reduced, are not consistently reduced to castrate levels with this strategy.

Safety and Efficacy

The physiological effects of two sterilants (Calcium chloride dehydrate and zinc gluconate buffered with arginine) have been described. In a pioneering study, [Jana and Samanta \(2011\)](#) tested the effects of intra-testicular injection of 0.25 mL of 5%, 10% and 20% calcium chloride solution (with 1% lidocaine) and showed that the 10% solution induced necrosis of the seminiferous tubules as well as of the interstitial tissue. In a second study using zinc gluconate (13.1 mg zinc/mL), [Oliveira et al. \(2013\)](#) have established that intratesticular injection (0.3 mL) to male cats (using a similar injection strategy as above) induced testicular atrophy and a drop in the presence of testosterone-dependent penile spines. Histological analysis of testes of treated cats showed a lack or very few germ cells within the seminiferous tubules, with clusters of Leydig cells remaining at some places.

Intra-testicular calcium chloride injection is usually done by inserting a 27 gauge needle into one pole of the testis and pushing it towards the other pole to ensure a homogeneous spread of the sterilant through testicular tissue. Such a treatment does not appear to be painful and mild discomfort is only observed during the minutes following injection. Testicular size usually increases following injection with the peak size reached within 2–4 days later. This early rise in testicular size is followed by a decrease over the next 2–4 weeks ([Kutzler, 2015](#)). Based on the damage done to the intra-testicular structures, it is assumed that the treated animals are sterile after a 4–6 weeks delay (linked to the exhaustion of the sperm reserves present in the epididymis). However, there is no solid clinical information documenting the ability to mate and fertility of treated tom cats in the long term.

The zinc solution approved by US FDA for use in male dogs 3–10 months of age (Zeuterin, Ark Sciences, previously known as Neutersol) has been extensively tested in these young dogs to document its safety and efficacy. A very low occurrence of injection site reactions has been reported in male dogs and cats (review: [Kutzler \(2015\)](#)). Apart from a transient testicular swelling on the day post injection, no testicular pain or tenderness were detected. On day 60 post injection, 91% of the tom cats were azoospermic and most of them displayed a reduction in testosterone dependent penile spines, suggesting a reduction in circulating testosterone concentrations. On day 120 post treatment, only 73% of the tom cats were azoospermic while the others displayed asthenospermia or teratospermia. Whether testicular function may remain fully suppressed over extended durations of time is yet to be demonstrated.

The Available Solutions for Treating Testosterone Dependent Diseases (GnRH Vaccine or GnRH Implants)

In pets (dogs and cats as well as horses) the expression of sexual behavior, a feature partly related to testicular testosterone production, may make animals unsuitable pets. In addition, in horses it may strongly interfere with performance during training and competition. In addition, in aging intact male dogs, benign prostatic hyperplasia, a testosterone dependent pathology, is common. Finally, in breeding stallions, the presence of the equine arteritis virus (AEV) in the accessory sex glands and in the ejaculate carries the risk of spreading the disease at each mating. In this case, viral persistence is known to be testosterone dependent and reduction of testosterone concentrations for a long enough period appears to be a suitable approach to “clean” AEV shedder stallions.

Purpose and Mode of Action

For these indications (behavior, benign prostatic hyperplasia and EAV treatment), a contraceptive treatment depressing testosterone concentrations may be useful. This may involve using GnRH vaccination, or a GnRH agonist implant. In EAV shedder stallions, the

effects of treatment should be reversible to allow them recovering a normal endocrine and exocrine testicular function, and breeding, if desired.

Efficacy and Safety

There are no studies that clearly demonstrate the link between the suppression of testosterone to the change in behavior in dogs, and more data are needed. Reduction of testosterone in male dogs, either by castration or one of the methods listed above, causes reduction in the size of the prostate gland. In AEV shedder stallions, [Burger et al. \(2006\)](#) demonstrated the efficacy of GnRH immunization to reduce testosterone concentrations and remove all EAV viral contamination from the male genital tract. This study did not report any issues with treatment's safety.

Conclusions

Three main strategies (GnRH vaccination, GnRH agonist implantation and injection of intra-testicular sterilants) have been shown to be useful for contraception in males. These options are the end result of years of active research aiming to provide solutions to the diversity of issues associated with raising/keeping intact males. In spite of significant research, only a few of these options have achieved regulatory approval in some markets, although they may be used off label for specific clinical needs. Many other treatments options (such as immunization against the LH receptor, or selective destruction of the pituitary gonadotropin secreting cells by GnRH-toxin conjugates) have also been studied without demonstrating that they reach the level of efficacy or duration to be practical for clinical use. Novel scientific breakthroughs may help to revive interest in these strategies. The area where active research remains mostly needed is the development of a life-long contraceptive treatment (perhaps by adeno associated virus mediated gene therapy) that could become an alternative to surgical castration of pets and, if accepted by the consumers, also in farm animals.

Introduction

Spermatogenesis is composed of a series of complex cellular events that take place in the seminiferous tubule – the functional unit of the testis that produces spermatozoa. These cellular events include: (i) self-renewal of spermatogonial stem cells (SSCs) and undifferentiated spermatogonia, (ii) meiosis I/II to generate haploid spermatids, (iii) postmeiotic spermatid development through spermiogenesis, and the release of mature spermatids (i.e., spermatozoa) at spermiation (Ehmcke and Schlatt, 2006; Schlatt and Ehmcke, 2014; Sharpe, 1994; O'Donnell, 2014; O'Donnell et al., 2006; de Kretser and Kerr, 1988). Furthermore, many of these cellular events including (ii)–(iv) take place in a specialized microenvironment known as the adluminal (apical) compartment of the seminiferous epithelium (Fig. 1). In short, cellular events pertinent to self-renewal of SSCs and undifferentiated spermatogonia, and the subsequent differentiation of type B spermatogonia to preleptotene spermatogonia take place in the basal compartment of the epithelium. But all cellular events pertinent to (ii)–(iv) that take place in the mammalian testis are behind the blood-testis barrier (BTB) (Fig. 1). Thus, cellular events pertinent to meiosis, spermiogenesis and spermiation are protected by the BTB – one of the tightest blood-tissue barriers, which also divides the epithelium of the seminiferous tubule into the basal and the adluminal (apical) compartments (Cheng and Mruk, 2012; Franca et al., 2012; Stanton, 2016; Pelletier, 2011). It is of interest to note that seminiferous tubules in the testis also maintain a daily production of ~70 million of sperm in an adult male rat versus ~300 million of sperm in an adult man (Johnson et al., 1980, 1983, 1984; Amann and Howards, 1980) through spermatogenesis. Thus, there is an enormous cellular output that takes place in the testis throughout the entire adulthood of any male. In order to protect spermatogenesis, besides the BTB, the testis is equipped with an array of drug transporters, either expressed by Sertoli or germ cells (or both) to avoid the passage of harmful substances and xenobiotics into the adluminal compartment to perturb spermatogenesis (Qian et al., 2013; Mruk and Cheng, 2012; Mruk et al., 2011; Setchell, 2008; Su et al., 2011). Despite the unique morphological settings in the testis to protect spermatogenesis, the testis, however, is highly sensitive to toxicants as noted in earlier studies, such as when rodents were exposed to cadmium or other toxicants more than six decades ago (Parizek and Zahor, 1956; Parizek, 1960; Kanakis and Goullis, 2015; Boekelheide et al., 1989, 2003, 2005). Since then, studies reporting the disruptive effects of toxicants, including heavy metals, plasticizers, and surfactants on male reproductive health including humans, such as reducing sperm counts, perturbing human sperm chromatin integrity, and causing idiopathic infertility in men in particular the epigenetic effects of male infertility have grown exponentially (Nordkap et al., 2012; Delbes et al., 2010; Cheng et al., 2011; Guerrero-Bosagna and Skinner, 2014). Herein, we focus our discussion on toxicants which induce disruption of endocrine systems in both humans and rodents known as EDCs (endocrine disrupting chemicals), by focusing on their effects in the testis in vivo or Sertoli cells cultured in vitro (Table 1). In brief, EDCs are agents that can interfere with the synthesis, secretion, metabolism, binding, and action of naturally occurring hormones in the body that are used for the maintenance of reproduction, development and/or behavior. As such, numerous environmental toxicants which are common EDCs that are known to cause testis injuries can be broadly categorized into three types, namely heavy metals (e.g., cadmium, mercury, lead), plasticizers (e.g., bisphenol A (BPA), phthalates), and surfactants (e.g., perfluorooctanesulfonate (PFOS), PFOA (perfluorooctanoic acid)) (Table 1). Since the subject of testis toxicants has been widely reviewed (O'Donnell, 2014; Boekelheide et al., 2000, 2003, 2012; Wan et al., 2013; Siu et al., 2009a; Wong et al., 2010; Johnson, 2014; Boekelheide, 2005), instead of providing a redundant review of the subject, we elect to provide a timely review based on recent studies regarding the likely common molecular targets of several EDCs. This information, in our opinion, is of interest not just to research scientists, but possibly clinicians since these recent studies have illustrated some potential candidates through which the toxicant-induced testis injury can possibly be therapeutically managed or treated, thereby providing a means to interfere toxicant-induced Sertoli cell injury. While we may not be able to reverse the toxicant-induced permanent damage to the testis, such as the BTB disrupted by an acute dose of cadmium, but proper preventive measures can be developed to help industrial workers to prevent testis injuries or manage toxicant-induced reproductive dysfunction. This is the goal of this review.

Fig. 1 A schematic drawing that illustrates the morphological features of the seminiferous epithelium from an adult rat testis. The blood-testis barrier (BTB) comprised of actin-based tight junction, basal ES and gap junction, as well as intermediate filament-based desmosome, which divides the seminiferous epithelium into the basal and the adluminal (apical). Endocrine disrupting chemicals (EDCs) enter the testis through the microvessels, some of which perturb Leydig cell steroidogenesis, perturbing gene expression through a disruption of androgen receptor (AR) function. Other EDCs perturb Sertoli cell function by modulating FSH receptor activity, perturbing spermatogenesis.

Cytoskeletons Are the Target of Environmental Toxicants

Studies using various toxicants, such as 2,5-hexanedione, carbendazim, colchicine, cadmium (e.g., CdCl_2), PFOS, BPA, and adjuvant (which is being investigated as a reversible male contraceptive and it has no considerable effects on either serum FSH, LH, testosterone or inhibin B in the treated animals Cheng et al., 2005; Mruk and Cheng, 2008; Mruk et al., 2008) have shown that Sertoli cell cytoskeletons including the actin- and/or microtubule (MT)-based cytoskeletons are the primary target of multiple toxicants (Boekelheide et al., 1989, 2003; Johnson, 2014; Boekelheide, 1993; Cheng, 2014; Siu et al., 2009b; Li et al., 2016a; Wan et al., 2014a; Gao et al., 2017) (Table 1). For instance, it has been reported that colchicine and carbendazim that induce germ cell sloughing is mediated primarily by Sertoli cell microtubule disruption (Boekelheide et al., 1989; Allard et al., 1993; Nakai and Hess, 1994;

Table 1 Disruptive effects of environmental toxicants or drugs on adult rodent testes in vivo or Sertoli cells cultured in vitro

Toxicant or drug	Phenotypes	Treatment dose(s)	Species	References
PFOS	Sertoli cell injury due to (i) mislocalization of Arp3 and palladin, (ii) disruptive organization of F-actin- and MT-based cytoskeletons; (iii) an up-regulation of p-rpS6 coupled with a down regulation of p-Akt1-S473 and p-Akt2-S474 that led to Sertoli cell TJ-permeability disruption	In vitro: 20–50 μ M	Rat/primary SC cultures	Gao et al. (2017)
	Loss of BTB integrity due to (i) p38/ATF2 activation, (ii) down-regulation of MMP9, occludin, and Cx43	In vivo: 0.5–10 mg/kg/b.w.	Mouse	Qiu et al. (2016)
	Sertoli cell injury due to down-regulation of the GJ protein Cx43	In vitro: 20 μ M	Rat/primary SC cultures	Li et al. (2016a)
	Sertoli cell TJ-barrier disruption due to: (i) disruptive F-actin organization as a result of truncation of actin filaments; (ii) disruptive inter-Sertoli cell gap junction (GJ) communication as a result of down-regulating of C43	In vitro: 10–20 μ M	Rat/primary SC cultures	Wan et al. (2014b)
BPA	An increase in Sertoli cell autophagy activity and cell apoptosis; an increase in Bax:Bcl-2 ratio	In vitro: 100–600 μ M	Goat/primary SC cultures	Zhang et al. (2017)
	BTB injury due to a down-regulation of occludin, ZO-1, β -catenin, AR and TGF- β 2	In vitro: 20 μ M	Human/ primary SC cultures	de Freitas et al. (2016)
	Sertoli cell apoptosis; down-regulation of Bcl-2; up-regulation of CaM and caspase-3 expression; increase in CaMKII phosphorylation	In vitro: 20 μ M	TM4 cell line	Qian et al. (2014)
Cadmium	Sertoli cell injury, BEX4 up-regulation	In vivo: 3.5 mg/kg	TM4 cell line	Yu et al. (2017)
	Reduced Sertoli cell migration with impaired cell viability, a loss in actin and tubulin expression and a reduced phosphorylation status of the MTs and actin microfilaments; down-regulation of F-actin cleavage protein cofilin and MT polymerization inhibitory protein stathmin	In vitro: 1 and 12 μ M	TM4 cell line	Egbowon et al. (2016)
	BTB injury, likely mediated by: (i) an up-regulation in extracellular matrix regulatory protein dermatopontin expression, and (ii) a down-regulation in claudin-11 expression	In vivo: 3.5 mg/kg b.w.	Mouse	Yang et al. (2014)
Adjudin	Premature release of elongating/elongated spermatids, followed by round spermatids and spermatocytes mediated by a down-regulation of Eps8, formin 1, EB1, and MARK4; and an up-regulation of Arp3	In vivo: 50 mg/kg/ b.w.	Rat	Li et al. (2017b)
	BTB injury due to a down-regulation of Cx43, which impeded meiosis and spermiogenesis; overexpression of Cx43 rescued the adjudin-induced BTB injury, resealing the BTB and re-initiating spermatogenesis	In vivo: 125 mg/kg/b.w.	Rat	Li et al. (2016b)
Triptolide	Sertoli cell injury, likely due to a down-regulation of β -actin, Rho GTPase (e.g., RhoA, RhoB, Cdc42 and Rac1) expression	In vivo: 100 μ g/kg/ b.w.	Rat	Wang et al. (2016)
	Testis injury due to a failure in intracellular transport of fatty acids and a down-regulation of PPARs	In vivo: 60 μ g/kg/ b.w.	Mouse	Ma et al. (2015)

Lim and Miller, 1997; Nakai et al., 1992). Carbendazim exerts its disruptive effects by blocking tubulin polymerization (Johnson, 2014; Winder et al., 2001). As such, MTs no longer are capable of undergoing the dynamic restructuring to confer germ cell adhesion and other crucial endocytic vesicle-mediated protein trafficking events (e.g., protein endocytosis and recycling), as well as the transport of spermatids and organelles (e.g., residual bodies, phagosomes) across the epithelium to support spermatogenesis, thereby causing defects in spermatogenesis and infertility in rodents. In this context, it is of interest to note that this disruptive effect is stage-specific, and spermatids that are embedded deep inside the seminiferous epithelium, such as in stages I–V, are less susceptible to carbendazim-induced loss (Nakai et al., 2002). Subsequent studies using the adjudin model have shown that this is likely due to the gross disruption of the track-like structures conferred by either MTs and/or F-actin across the seminiferous epithelium, thereby depleting the ability of the Sertoli cells to support spermatid transport across the epithelium so that spermatids can be released to the tubule lumen similar to those spermatids residing near the tubule lumen (Tang et al., 2016). This possibility is supported by the observation that the anchoring device between Sertoli cells and elongated spermatids known as the apical ES has been grossly disrupted by adjudin for spermatids resided near the tubule lumen, but also for spermatids embedded deep inside the epithelium (Tang et al., 2016). Furthermore, treatment of rats with glycerol following intratesticular injection (Wiebe and Barr, 1984; Wiebe et al., 1989) was also found to cause gross disruption of microtubules and actin microfilaments (Wiebe et al., 2000). Similarly, treatment of rats with CdCl₂ was also found to induce defragmentation of the actin microfilaments and actin-based TJ fibrils (Hew et al., 1993), illustrating the cytoskeleton is a target of many toxicants. In order to better define the molecular mechanism(s) underlying toxicant-induced cytoskeletal disruption, we had used Sertoli cells cultured in vitro as a study model to examine the biology of toxicant-induced cytoskeleton dysfunction including studies in both rat (Li et al., 2016a; Wan et al., 2014a; Gao et al., 2017) and human Sertoli cells (Xiao et al., 2014). Based on these studies, it is increasingly clear that the toxicant-induced cytoskeletal dysfunction in Sertoli cells utilizes similar mechanistic pathways and signaling molecules both in vitro and in vivo. These findings, if adequately expanded to cover additional toxicants, should be helpful for future studies designed to interfere with the toxicant mediated Sertoli cell injury by blocking or activating specific signaling pathways and/or signaling molecule(s).

Toxicants-Induced Sertoli Cell Injury Through Cytoskeletal Disruption Is Mediated by Changes in the Spatial Expression of Actin- and MT-Binding and Regulatory Proteins

When Sertoli cells are cultured in vitro for ~2–3 days, distinctive actin filaments and also microtubules (MTs) are clearly visible which stretch across the entire cell cytosol (Gao et al., 2017) (Table 1). These track-like ultrastructures are essential to support Sertoli cell shape and provide structural support for cellular transport of endocytic vesicles, phagosomes, and other organelles to maintain cellular homeostasis. However, following exposure of these cells to PFOS for 24 h, F-actin was truncated, failing to stretch across the entire cell cytosol (Gao et al., 2017). Interestingly, it was noted that these changes were the result of disruptive spatial expression of the actin bundling protein palladin and also branched actin nucleation protein Arp3 (Gao et al., 2017). In this context, it is of interest to note that palladin confers actin microfilaments to a bundled configuration to support Sertoli cell adhesion, such as at the Sertoli cell blood-testis barrier (BTB). On the other hand, actin-related protein 3, which together with the Arp2, create the Arp2/3 complex known to induce branched actin polymerization when activated by N-WASP (neuronal Wiskott-Aldrich syndrome protein), effectively converting a linear actin filament to a branched configuration, thereby making actin filament bundles to become a branched network. Thus, the combined action of palladin and the Arp2/3 complex would provide the plasticity to the actin filaments, necessary to changes Sertoli cell shape in response to the stage of the epithelial cycle to support spermatogenesis. However, treatment of Sertoli cells to PFOS for 24 h led to disruptive changes in the spatial expression of both Arp3 and palladin but also p-FAK-Tyr407 which is known to promote Sertoli cell BTB function through its effects to maintain actin-cytoskeletal function (Lie et al., 2012). As the actin-based cytoskeleton was disrupted by PFOS due to unwanted changes in the spatial expression of these actin regulatory proteins, the Sertoli cell TJ-permeability barrier function was also disrupted (Wan et al., 2014a). Since virtually all the adhesion protein complexes at the Sertoli cell BTB, such as the TJ (e.g., CAR (coxsackievirus and adenovirus receptor)/ZO-1 (zonula occludens-1)) and basal ES (N-cadherin/ β -catenin) adhesion protein complexes utilize actin for their attachment, the disorganization of actin filaments in Sertoli cells thus led to gross mis-localization of CAR, ZO-1, N-cadherin and β -catenin at the Sertoli cell cortical zone (Gao et al., 2017). These observations are also consistent with results of an earlier report in which treatment of PFOS for 24 h at 20 μ M would induce mis-localization of TJ and basal ES proteins at the Sertoli cell-cell interface (Wan et al., 2014a). While these findings are of interest, it is not known if similar changes could be observed in humans. Interestingly, studies using human Sertoli cells cultured in vitro (Chui et al., 2011) indeed have shown that treatment of human Sertoli cells with either CdCl₂ (5 or 20 μ M) or BPA (0.4, 40 or 200 μ M) also impedes the organization of F-actin, causing truncation of actin microfilaments (Xiao et al., 2014). This, in turn, perturbs the localization ZO-1 (a TJ adaptor protein), and N-cadherin and β -catenin (a basal ES adhesion protein complex) at the Sertoli cell cortical zone, making them diffusively localized at the BTB site (Xiao et al., 2014). More important, these changes are likely contributed by the disruptive spatial expression of Arp3 and Eps8 (epidermal growth factor receptor pathway substrate 8, an actin barbed end capping and bundling protein, conferring actin filaments to a bundled configuration (Ahmed et al., 2010; Cheng and Mruk, 2011)) and also c-Src (Xiao et al., 2014) (note: c-Src and its closely related member c-Yes within the Src family kinases (SFK) were earlier shown to be involved in modulating F-actin organization in Sertoli cells (Xiao et al., 2011, 2013)). For instance, following exposure of human Sertoli cells cultured in vitro to BPA (200 μ M) or CdCl₂ (20 μ M) for 24 h, Arp3, Eps8 and c-Src no longer evenly distributed across the human Sertoli cell cytosol and the cell cortical zone, instead, they were found to be retracted and moved closer to the cell nuclei, thereby failing to support the F-actin network across the cell to maintain adhesion protein complexes at the cell-cell interface (Xiao et al., 2014).

Role of p-FAK-Tyr407 in Toxicant-Induced Sertoli Cell Injury

FAK and its phosphorylated forms (such as p-FAK-Tyr397 and p-FAK-Tyr576) were initially shown to be involved to spermatid adhesion in early 2000s when these proteins were found to be intensively localized at the apical ES in stage VII-late VIII tubules (Siu et al., 2003, 2005; Beardsley et al., 2006). These findings were later expanded, developing into a novel concept that p-FAK-Tyr397 and/or p-FAK-Tyr576 may be working in concert with the Sertoli cell-specific adhesion protein $\alpha 6 \beta 1$ -integrin to support apical ES function, serving as a novel signal protein that contributes to the release of sperm at spermiation (O'Donnell et al., 2011; O'Donnell, 2014; Cheng and Mruk, 2015). Subsequent studies have shown that another FAK isoform, p-FAK-Tyr407, is playing a crucial role to support Sertoli cell adhesion function at the BTB as well (Lie et al., 2012). Using different phosphomimetic mutants versus nonphosphorylatable mutants of p-FAK-Tyr397 and p-FAK-Tyr407, it was shown that p-FAK-Tyr397 and p-FAK-Tyr407 supports apical ES and basal ES/BTB function, respectively (Lie et al., 2012). For instance, overexpression of the phosphomimetic mutant of p-FAK-Tyr407, namely p-FAK-Y407E mutant (in which Tyr-407 was mutated to Glu-407, making it a constitutively active mutant) or a constitutively inactive mutant of p-FAK-Tyr397, namely p-FAK-Y397F mutant (in which Tyr-397 was mutated to Phe-397, making it a constitutively inactive mutant) in Sertoli cells, they would both promote the Sertoli cell TJ-permeability barrier function (Lie et al., 2012). Furthermore, the promoting effect of p-FAK-Y407E mutant to the Sertoli cell TJ-barrier function is mediated by increasing the Sertoli cell actin nucleation function (Lie et al., 2012). These findings are important since they illustrate p-FAK-Tyr407 exerts its effects by making the Sertoli TJ-barrier "tighter" is mediated through changes in the organization of F-actin across the Sertoli cells. Subsequent studies by using an endogenous produced miRNA, called miR-135, which is known to knockdown FAK specifically in rats (Linsen et al., 2010; Landgraf et al., 2007), was capable of perturbing F-actin organization in Sertoli cells, potentiating the disruptive effects of PFOS (20 μ M) (Wan et al., 2014a). More important, it was also shown that treatment of PFOS also down-regulated the expression of connexin 43 (Cx43, a Sertoli cell integral membrane protein that constitutes the gap junction (GJ) in the rat testis) considerably (Wan et al., 2014a). Additionally, this considerable down-regulation of Sertoli cell Cx43 expression also perturbed the Sertoli intercellular GJ communications based on a fluorescence recovery after photobleaching (FRAP) functional assay (Wan et al., 2014a). Subsequent studies have shown that overexpression of Cx43 in Sertoli cells can rescue the PFOS-induced Sertoli cell GJ dysfunction by re-establishing the GJ communication between Sertoli cells (Li et al., 2016a). Furthermore, overexpression of Cx43 in Sertoli cells also prevent the PFOS-induced F-actin dis-organization (Li et al., 2016a). Taking collectively, these data thus illustrate the PFOS-induced Sertoli cell injury is mediated through a disruption of Sertoli cell GJ-based communication function, involving p-FAK-Tyr407, which in turn perturbs the F-actin organization in Sertoli cells.

Role of mTORC1-p-rpS6-p-Akt1/2 Signaling Pathway in Toxicant-Induced Sertoli Cell Injury

mTOR (mammalian target of rapamycin), a well conserved Ser/Thr protein kinase across different species including flies, worms and mammals, is an ubiquitous signaling molecule found in virtually all mammalian cells including Sertoli and germ cells in the testis (Shimobayashi and Hall, 2014; Laplante and Sabatini, 2012). It supports a wide range of cellular functions and pathological conditions including energy metabolism, protein synthesis, cell growth, cell survival, differentiation, cytoskeletal dynamics, maintenance of pluripotency of stem cells, cell signaling, tumorigenesis, and others (Bockaert and Marin, 2015; Stransky et al., 2016; Goodman, 2014; Ito and Suda, 2014; Mok et al., 2013). When mTOR binds to adaptor protein Raptor (regulatory-associated protein of mTOR) or Rictor (rapamycin-insensitive companion of mTOR), it creates the mTORC1 (mammalian target of rapamycin complex 1, i.e., mTOR+Raptor) or mTORC2 (mammalian target of rapamycin complex 2, i.e., mTOR+Rictor), respectively. Studies have shown that mTORC1 exerts its regulatory effects downstream through rpS6 (ribosomal protein S6) and Akt1/2 (Borrie et al., 2017) by affecting Sertoli cell TJ-barrier function, making the immunological barrier "leaky" (Mok et al., 2012, 2014, 2015) (Fig. 2). For instance, treatment of Sertoli cells cultured in vitro with rapamycin or a knockdown of rpS6 by RNAi was found to promote the Sertoli cell barrier, making its "tighter" (Mok et al., 2012), illustrating its physiological function during the epithelial cycle promotes BTB disruption, making it "leaky". Indeed, overexpression of rpS6 or a quadruple phosphomimetic mutant, by mutating S235, S236, S240 and S244 to E235, E236, S240 and S244 by site directed mutagenesis to create a constitutively active form of rpS6, in Sertoli cells was found to induce disruption of the Sertoli cell TJ-barrier (Mok et al., 2014, 2015). More important, these changes were also associated with an extensive disruption on the organization of the Sertoli F-actin network in which actin microfilaments across the Sertoli cells were grossly truncated (Mok et al., 2015). Since these studies were based on the use of Sertoli cells in vitro, the physiological relevancy of this information to the testis in vivo was not established. Interestingly, a recent study by overexpressing rpS6 wild type (WT, i.e., full-length rpS6 cDNA) versus p-rpS6-mutant (i.e., the quadruple constitutively active mutant of rpS6) and empty vector (i.e., the mammalian expression vector pCI-neo alone) in the testis in vivo was found to induce damage to the BTB in vivo (Li et al., 2017a). Additionally, considerably more severe damaged was detected following overexpression of p-rpS6 mutant versus rpS6-WT based on the use of a functional assay to assess the BTB integrity and when defects of spermatogenesis in the testis were assessed by histological analysis (Li et al., 2017a). In this context, it is of interest to note that earlier studies using Sertoli cells cultured in vitro have shown that mTORC1 exerts its disruptive effects on the Sertoli cell TJ-barrier function is mediated by an up-regulation rpS6, which is associated with a considerable down-regulation of Akt1/2 expression downstream (Mok et al., 2014, 2015), illustrating Akt1/2 is part of the mTORC1/rpS6 signaling pathway (Fig. 2). Interestingly, exposure of Sertoli cells cultured in vitro to PFOS at 50 μ M indeed caused a considerable down-regulation of Akt1/2, associated with consideration dis-organization of F-actin and also MT across the Sertoli cell cytosol (Gao et al., 2017), implicating

Fig. 2 A possible mechanism by which PFOS induces Sertoli cell injury through disruptive changes in Sertoli cell actin- and MT-based cytoskeletons. (see text for details).

Akt1/2 may be the signaling molecule involving in the PFOS-mediated Sertoli cell injury. When a Akt1/2 activator SC79 was included in the Sertoli cell cultures together with PFOS treatment, it was shown that SC79 was capable of blocking the PFOS-induced actin- and MT-based disruption (Gao et al., 2017) (Fig. 2). SC79 was also found to block the PFOS-induced changes in the disruptive spatial expression of p-FAK-Tyr407 (Gao et al., 2017). These findings are significant since they illustrate that the mTORC1-rpS6-pAkt1/2 and p-FAK-Tyr407 signaling proteins may be working in concert to modulate the organization of Sertoli cell actin- and MT-based cytoskeletons, but they are also one of the targets of toxicants. In short, these findings, if adequately expanded in future studies, may provide a novel approach to therapeutically manage toxicant-induced Sertoli cell and testis injury.

Concluding Remarks and Future Perspectives

Based on some recently published findings, we provide herein insightful information regarding the underlying molecular mechanism(s) in particular the cellular targets and signaling proteins that are involved in toxicant-induced Sertoli cell and testis injury. The use of human Sertoli cells cultured *in vitro* as a study model is of considerable help to relate findings based on the use rodent testicular cells to humans. It is increasingly clear that the Sertoli cell actin- and MT-based cytoskeletons are the target of toxicants based on studies using PFOS, BPA and cadmium. We have also identified p-FAK-Tyr407 and mTOR-rpS6-Akt1/2 signaling proteins are possibly working in concert to modulate PFOS-induced testis and Sertoli cell injury, involving both actin- and MT-binding regulatory proteins. Many questions remain unanswered. For instance, what is the upstream molecule(s) that trigger or regulate p-FAK-Tyr407 and mTORC1/rpS6/Akt1/2 signaling proteins? How does an activation of p-FAK-Tyr407, mTORC1, rpS6 or Akt1/2 relate to changes in the organization of F-actin and/or MTs? Does this involve any small GTPases, such as Rho and Rac GTPases? It is expected that some of these questions will be answered in the upcoming years when more data are available in the field. It is also expected that some of the unexplained infertility caused by environmental toxicants could be therapeutically managed when additional information is available based on studies using the human Sertoli cell model.

Nuclear Receptors Are Primary Targets of EDCs

Most of the reported harmful effects of EDCs are currently attributed to their interference with hormonal signaling mediated by nuclear receptors (NRs) (Guilivo et al., 2016). Human NRs are a family of 48 ligand-regulated transcription factors that control a plethora of biological processes such as development, organ homeostasis, metabolism, immune function, or reproduction. As a consequence, inappropriate exposure to EDCs, can cause proliferative reproductive and metabolic disorders, including hormonal cancers, infertility, and obesity. NRs harbor transcription regulation as well as DNA- and ligand-binding properties embedded in three distinct structural domains, and respond to a large variety of small endogenous agonist ligands such as hormones, vitamins, fatty acids or metabolites. Upon binding of agonist ligands, conformational changes in the C-terminal region of the ligand-binding domain (LBD) allow NRs to recruit transcriptional activators. Reciprocally, interactions with antagonists enable repressors recruitment. Most of the studies on EDCs have originally focused on NRs involved in reproductive processes, in particular the estrogen (ER α and ER β) and the androgen (AR) receptors. More recently, studies have shown that the activity of the retinoid X receptors (RXRs), the peroxisome proliferator-activated receptors γ (PPAR γ) or the pregnane X receptor (PXR) is also modulated by EDCs.

The group of molecules acting as environmental ligands of NRs is highly heterogeneous and comprises compounds that are often distantly related to endogenous ligands in terms of size or chemical structure. This group contains substances as chemically different as bisphenols, phthalates, parabens, dioxins, alkylphenols, organotins, polychlorinated biphenyls, perfluoroalkyls, or benzophenones, as well as natural compounds. This large structural diversity renders the interaction of EDCs with their biological targets barely predictable. Most of the studies have revealed that chemicals bind to NRs with medium affinities ranging from sub to high micromolar (le Maire et al., 2010). However, recent studies have revealed some binding modes by which EDCs achieve high affinity binding to NRs. Since humans and wildlife are simultaneously and chronically exposed to low doses of multiple contaminants, understanding the molecular mechanisms underlying the physiological consequences of exposure to environmentally relevant concentrations of EDCs is of prime importance.

The Estrogen Receptors

ER α and ER β (NR3A1-2) are receptors for the sex hormone 17 β -estradiol (E2), that plays important roles in the growth and maintenance of a diverse range of tissues such as the mammary gland, uterus, bone or the cardiovascular system. Furthermore, estrogens are key regulators of primary breast, endometrial, and ovarian cancer growth. Both ERs are widely distributed throughout the body, displaying distinct but overlapping expression patterns in a variety of tissues (Couse and Korach, 1999). Although ER α and ER β share similar mechanisms of action, several differences in the transcriptional abilities of each receptor as well as distinct phenotypes between gene null animals have been identified, suggesting that these receptors may regulate distinct cellular pathways (Couse and Korach, 1999).

Endogenous estrogens (estradiol, estriol, estrone) are high affinity ligands of ERs with dissociation constants (K_d s) in the subnanomolar range. On the contrary, xenoestrogens such as the phytoestrogens genistein and ferutinin, the metabolites of pesticides DDE, HPTE, and M2 compound (respectively DDT, methoxychlore, and vinclozolin metabolites), the plasticizers bisphenols and phthalates, and the benzophenones and parabens used as UV filters and preservatives, respectively, bind to ERs with affinities in the sub- to micromolar range which is far above the environmental concentrations (Table 1). All of them bind to the hormone-binding site of ERs and engage in different sets of ligand/protein interactions according to their size and chemical structures. The smallest compounds making fewer contacts with the receptor cavity are generally associated with lower binding affinities whereas bigger EDCs adopting a binding mode reminiscent of that used by the endogenous ligands are characterized by higher interaction capacities. This is for example the case of the mycoestrogens α -zearalanol (α -ZA) and its derivatives which bind and activate ERs with high affinity (Table 1). Comparison of the crystal structures of ER α in complex with E2 and α -ZA (Delfosse et al., 2014a), reveals that, even though the mycoestrogen is not a steroidal compounds, it recapitulates most of the interaction network observed with E2.

The Androgen Receptor

Androgen receptor (AR) (NR3C4) plays a crucial role in the regulation of target genes expression in physiological processes like development and differentiation of the male embryo, spermatogenesis initiation and maintenance, as well as neuroendocrine

Table 1 EDCs and their NR targets

EDCs	NR targets	Affinity	Environmental compounds	Nature
Natural estrogens	ER α , ER β	High	E2	Agonist
	GPR30	Controversial	E2	Agonist
	PXR	Low	E2	Agonist
Pharmaceuticalestrogens	ER α , ER β	High	EE2	Agonist
	PXR	Low	EE2	Agonist
Alkylphenols	ER α , ER β	Medium	4-tert-Octylphenol	Agonist
	AR	Low	4-tert-Octylphenol	Antagonist
	PXR	Low	4-tert-Octylphenol	Agonist
Benzophenones	ER α , ER β	Medium	BP2, THB	Agonist
	AR	Low	BP2, THB	Antagonist
Bisphenols	ER α , ER β	Medium	BPA	Agonist
	GPR30	Controversial	BPA	Agonist
	AR	Medium	BPC	Antagonist
	PXR	Low	BPA	Agonist
Halogenated bisphenols	ER α , ER β	Low	TetrachloroBPA	Agonist
	PPAR γ	Low	TetrachloroBPA	Agonist
Mycoestrogens	ER α , ER β	High	α -zearalanol	Agonist
	AR	Low	α -zearalanol	Antagonist
	PXR	Low	α -zearalanol	Agonist
Organotins	PPAR γ	High	TPropT	Agonist
		High	TBT	Agonist
Parabens	ER α , ER β	Low	Butyl paraben	Agonist
Perfluorinated compounds	PPAR γ	Low	PFOA	Agonist
Pesticides	ER α , ER β	Low	DDE, HPTE, M2	Agonist
	AR	Medium	M2 vinclozolin	Agonist
	PXR	Low	Pretilachlor, T NC	Agonist
Phytoestrogens	ER α , ER β	Medium	Genistein, ferutinin	Agonist
	PPAR γ	Low	Genistein	Agonist
Phthalates	ER α , ER β	Low	BBP	Agonist
	PPAR γ	Low	MEHP	Agonist

BP2, benzophenone 2; BPA, bisphenol A; BBP, benzyl butyl phthalate; DDE, dichlorodiphenyldichloroethylene; E2, estradiol; EE2, ethinil estradiol; MEHP, mono ethyl hexyl phthalate; PFOA, perfluorinated octanoic acid; TBT, tributyltin; THB, trihydroxy-benzophenone; TNC trans-nonachlore; TpropT, tripropyltin. K_d s of high affinity are lower than 1 nM. K_d s of medium affinity range from 1 nM to 1 μ M. K_d s of low affinity are higher than 1 μ M.

system functioning (Matsumoto et al., 2013). Furthermore, androgens are key regulators of primary prostatic growth. In the absence of ligand, AR is essentially localized in the cytoplasm. Binding to androgens enables heat shock proteins (hsps) dissociation and AR translocation to the nucleus. The presence of androgens is essential for the regulation of male embryo development and differentiation processes and spermatogenesis initiation and maintenance. Environmental compounds have been extensively studied for their action on AR and most of the compounds described as being estrogenic display also antiandrogenic activities. The most potent of them are (α -ZA) and its derivatives, the pesticides metabolites M2 compound and DDE, cosmetics like benzophenone 2 and some bisphenols such as BPA and BPC. The affinities of these diverse environmental antiandrogens are in the sub- to micromolar range (Table 1).

The Retinoid X Receptors

RXR α , β , and γ (NR2B1-3) occupy a central position in the NR superfamily as they are the common heterodimerization partners for one-third of the 48 family members including PPAR γ and PXR. As such, RXRs play key roles in the control of many NR-dependent signaling pathways. RXR ligands and ligands of the partner receptors can act synergistically to activate heterodimers (Germain et al., 2002). This regulatory control of nuclear signaling pathways by multiple RXR heterodimers allows environmental RXR ligands to potentially trigger a multitude of adverse effects on human health.

RXRs are activated by endogenous retinoids like 9-*cis* retinoic acid (9-*cis*RA) (Kd in the nanomolar range) and some other vitamin A metabolites and unsaturated fatty acids (Kds in the micromolar range). On the other hand, RXRs can be activated by some organotin compounds at nanomolar concentrations (Table 1). Organotins are ubiquitously present throughout the environment due to their widespread use since the 1960s in many industrial and agricultural processes. Since the 1980s, they were found to be responsible for a wide variety of deleterious effects in the endocrine systems of humans and wildlife at nanomolar concentrations. They do not, neither structurally nor chemically, resemble known NR ligands so the mechanism by which organotins act as endocrine disruptors has remained enigmatic until the crystal structure of RXR α in complex with tributyltin (TBT) was solved (le Maire et al., 2009). The structure shows that as compared with 9-*cis*RA, the organotin occupies only a small part of the ligand binding pocket (LBP). However, it also reveals that the high affinity of TBT for RXRs derives from the formation of a covalent bond between the tin atom of the organotin and the sulfur atom of the conserved cysteine in the LBP. Although TBT interacts with only a subset of LBP residues, it is engaged in enough essential contacts to efficiently stabilize RXR α in an active conformation which is crucial for the recruitment of transcriptional activators. Hence, in addition to bind to RXR at very low concentrations, TBT acts as a full agonist activating the receptor as efficiently as 9-*cis*RA.

The Peroxisome Proliferator Activated Receptor γ

The NR subfamily of peroxisome proliferator-activated receptors (PPARs) includes three members, PPAR α (NR1C1), PPAR β / δ (NR1C2), and PPAR γ (NR1C3). These receptors bind to PPAR-responsive DNA regulatory elements in the form of heterodimers with RXR. PPARs have distinct tissue distributions and physiological roles (Berger and Moller, 2002). PPAR α is preferentially expressed in the heart, liver, and brown adipose tissue, whereas PPAR β / δ is ubiquitously expressed. They both play an important role as activators of fatty acid oxidation pathways and thus in the regulation of energy homeostasis. PPAR γ , for its part, is highly expressed in adipose tissues and plays a key role in regulating adipogenesis, lipid metabolism, and glucose homeostasis by improving insulin sensitivity.

PPARs bind and respond to dietary fatty acids and various lipid metabolites, including eicosanoids, prostaglandins, and oxidized phospholipids. In accordance with their tissue distributions and roles as sensors of lipids/fatty acids levels, in regulating fatty acid catabolism, and in lipid storage, all three PPARs are thought to be strongly involved in the metabolic syndrome. However, in light of the particular role of PPAR γ in adipose tissue development and maintenance, it has been suggested that the disruption of regulatory pathways controlled by PPAR γ may be specifically implicated in the onset of diabetes and obesity. It was thus proposed that activation of PPAR γ by environmental compounds could contribute to the "obesogen hypothesis" stating that the growing obesity epidemic due to the imbalance between caloric intake and expenditure could also implicate chemicals, so-called "obesogens," which directly or indirectly increase fat accumulation and obesity.

As a matter of fact, activation of PPAR γ by some xenobiotic compounds like BPA and its halogenated derivatives, perfluorooctanoic acid, mono(2-ethylhexyl) phthalate (MEHP), phytoestrogens and organotins has been shown to stimulate adipogenesis *in vitro* and *in vivo* by promoting the differentiation of preadipocytes of the fibroblastic lineage into mature adipocytes (Delfosse et al., 2014b). With the exception of organotins that can bind to PPAR γ with nanomolar affinities, all of these compounds activate PPAR γ with EC50s in the micromolar range (Table 1). The crystal structure of PPAR γ in complex with the tripropyltin (Delfosse et al., 2014b) shows that the interacting cysteine anchors the organotin in a region of the LBP that does not allow the efficient stabilization of the active receptor conformation. This is in line with the weak PPAR γ agonistic activity of the compound. Interestingly, some of these environmental (BPA, MEHP) and pharmaceuticals (ibuprofene, indomethacine) PPAR γ ligands have also been shown to cause direct endocrine disorders in the human fetal testis and alteration of the germ cell biology (Albert and Jégou, 2014; Mazaud-Guittot et al., 2013).

The Pregnane X Receptor

Pregnane X receptor (NR1I2) is a broad-specificity sensor playing a critical role in the regulation of phase I oxidative enzymes, phase II conjugating enzymes, and phase III transport uptake and efflux transporters, co-ordinately regulating steroid, drug, and xenobiotic

clearance in the liver and intestine (Orans et al., 2005). Activated PXR binds to gene promoters as a heterodimer with RXR and triggers the expression of target genes such as the cytochrome P450 3A4 (CYP3A4), UDP-glycosyltransferase (UGT1A1), and multidrug resistance protein 1 (MDR1). PXR plays an important role in protecting the endocrine system from EDCs by sensing concentration increases of these chemicals and stimulating detoxification pathways, resulting in a decreased interaction of EDCs with other NRs. This PXR-driven elimination of xenobiotics confers a positive role to the activation of this NR. On the contrary, PXR activation can also prevent effects of endogenous hormones or drugs by stimulating prematurely their metabolism, which could lead to adverse interactions or harmful effects. In addition, the activation of PXR has been linked to chemoresistance, growth, and aggressiveness of colon and hepatic cancers (Banerjee et al., 2014).

Unlike many NRs that tend to be specialized to bind few ligands with structural homologies, PXR is able to interact with a large number of structurally diverse compounds with medium affinities (K_{ds} between 0.1 and 100 μM). Known ligands of PXR include pesticides, phenols, cosmetics, phytoestrogens, pharmaceuticals, etc. (Table 1) (Banerjee et al., 2014). Crystallographic studies have revealed the unique characteristics of PXR that account for its promiscuous ligand-binding properties. Firstly, PXR possesses a large LBP that can accommodate compounds with larger volumes than that of classical NR ligands, and secondly, several loops of the LBD confer a high plasticity allowing the receptor to adopt different shapes according to the bound ligands. A recent study demonstrated that a pharmaceutical estrogen (the contraceptive 17 α -ethinylestradiol, EE2) and a persistent organochlorine pesticide (*trans*-nonachlor, TNC), both exhibiting low efficacy when studied separately, cooperatively bind to PXR, leading to synergistic activation (Delfosse et al., 2015). High-resolution crystal structures showed that individually, EE2 and TNC are too small to make all the necessary interactions ensuring high binding affinity and effective stabilization of the active conformation of the receptor. In contrast, when associated in a binary mixture, EE2 and TNC fill a larger fraction of the PXR LBP. Strong interligand contacts between EE2 and TNC generate a mutual stabilization of the compounds in the LBP and account for the enhanced binding affinity of the binary mixture. This study provided the first detailed mechanistic explanation and a proof of concept for the synergistic action of a mixture of compounds (cocktail effect) via their simultaneous interaction with a NR, as well as a new insight on how low doses of EDCs or drugs may affect physiology and homeostasis.

Other Disruption Pathways of EDCs

Beside their interference with the NR signaling, EDCs could also interact with membrane-associated receptors (Fig. 1). It is now well accepted that a small amount of NRs, including ER α and β (mbER α and mbER β), are located at the membrane and could mediate the effects of xenoestrogens such as BPA or alkylphenols outside the nucleus (Nadal et al., 2017). It has been suggested that such

Fig. 1 Possible sites of action of EDCs on hormonal signaling.

rapid nongenomic activation of signal transduction pathways could explain the low-dose effects of EDCs, but this hypothesis is still controversial and needs further investigations (Arnal et al., 2017).

The G protein-coupled receptor 30 (GPR30) also referred to as G protein-coupled estrogen receptor (GPER) was also proposed to act as a nonclassical estrogen receptor localized at the plasma membrane (Revankar et al., 2005). However some recent data contradict this hypothesis suggesting that GPR30 would rather be a collaborator of mbERs (Levin, 2009).

Additionally, EDCs could also alter hormone actions by interfering with their synthesis, transport or metabolism (Fig. 1), and in turn, modify their physiologic concentrations. For instance, several pesticides have been reported to inhibit aromatase activity (CYP19) (Whitehead and Rice, 2006). This enzyme plays a crucial role in steroidogenesis because it allows the synthesis of estrogens (estradiol and estrone) from androgens (testosterone and androsterone). Thus, pesticide-induced inhibition of aromatase can lead to masculinization of an individual (human or animal) by increasing endogenous androgen concentrations and decreasing estrogen levels. The masculinising effect of organotins used in antifouling paints on female gastropods, which is termed “imposex,” was initially attributed to the inhibition of aromatase activity. However, the effective concentrations for aromatase inhibition by organotins are in the high micromolar range that largely exceeds their environmental doses. It is now assumed that the effects of tin compounds on CYP19 are by RXRs whose affinity for organotin compounds is in the nanomolar range (Nakanishi, 2008).

Many EDCs including flame retardants have also been suspected to disrupt thyroid function by binding to thyroid hormone transport proteins such as transthyretin (TTR) (Weiss et al., 2009). By inhibiting the binding of triiodothyronine precursor thyroxine to TTR, these compounds can lead to insufficient intracellular levels of thyroid hormones. However, these effects are rarely observed at concentrations below the micromolar range which is far above the concentrations of EDCs encountered in the environment (Hamers et al., 2006).

Another mechanism of action of EDCs is on hormonal clearance. Exposure to some EDCs may lead to an increase in the expression of metabolizing enzymes and transporting proteins that in turn increase hormonal clearance. For instance, the insecticide fipronil has been described as a thyroid hormone signaling disruptor by increasing thyroid hormones clearance. However, this effect is most likely indirect as fipronil has been shown to be an activator of PXR and the constitutive activated receptor (CAR) which are master regulators of the expression of many genes involved in xeno- and endo-biotics metabolism (Roques et al., 2013).

Concluding Remarks

EDCs represent a broad class of substances that are suspected to interfere with hormone synthesis, transport, degradation, or action, and thus alter the proper function of the endocrine system. Several research groups have proposed that the nonclassical GPER/GPR30 or mbERs could mediate the effects of xenoestrogens through rapid nongenomic activation of signal transduction pathways. However his hypothesis is still controversial and there is a urgent need to develop assays to detect low-doses extranuclear initiated actions of EDCs to further explore this hypothesis. As of today, the deregulation of NR-mediated transcription appears to account for most of the deleterious effects EDCs. Thus characterization of the interaction between NRs and environmental compounds is important for the assessment of the global hormonal activity of a large number of chemicals and the understanding of their mechanisms of action at environmentally relevant concentrations.

High affinity interaction between some EDCs and NRs could explain some of these effects. For instance, in spite of its structural differences with E2, the interaction of α -ZA (a mycoestrogen with nonestrogenic chemical structure) with ER α resembles that of E2. As a consequence, α -ZA is one of the most active xenoestrogen that can modulate ER activity at concentrations as low as 0.1 nM. In contrast, it has been shown that organotins such as TBT do not recapitulate any of the specific interactions made by the classical ligands of RXRs and PPAR γ with their corresponding receptors. Instead, tin compounds use a Sn-S covalent interaction to bind to and modulate the transcriptional activity of the RXR–PPAR heterodimer at nanomolar concentrations. It is thus not excluded that the low dose effects of some environmental compounds could also be explained by their covalent interaction with the dozen NRs containing a cysteine residue in their LBP. Accordingly, it has been reported that dibutyltin acts as a potent antagonist of the glucocorticoid receptor (GR) which contains two cysteine residues in its hormone-binding site. Finally, experimental evidences have been recently provided for the concomitant interaction of two EDCs with PXR. It was shown that the two compounds interact with each other in the PXR LBP, forming a more potent activator than either of the two chemicals alone. The two compounds not only bind concomitantly to the LBP of the receptor, but they do so cooperatively, that is, binding of one molecule promotes high affinity binding of the second. Structural studies revealed that the ligands mutually stabilize each other via strong interligand contacts and that a large number of interactions with LBP amino acids allow the so-called “supramolecular ligand” to tightly hold the receptor in the transcriptionally-competent conformation. A synergistic/additive effect resulting from the simultaneous activation or inhibition of different NRs could also account for the low dose action of certain chemicals. BPA, which is a moderate environmental agonist of ERs, PXR, and AR antagonist, is a good example of an EDC whose adverse effects could result from its combined estrogenic and antiandrogenic properties.

Temperature and Testis

Introduction

Mammals function at high core body temperatures (from approximately 35°C–39°C) obtained from combustion of fuel material to achieve heat production. Body temperature is closely regulated by matching heat production with heat loss to the environment via conduction, convection, radiation, and evaporation. Regulation of core body temperature is a priority over several other physiological functions, as endotherms can better tolerate low body temperatures than high body temperatures (Hansen, 2009). Most mammals have testes suspended in a scrotum outside the body cavity, and there is abundant evidence that in a thermoneutral environment the scrotal testes are appreciably cooler than the body, but this does not mean that they are kept at a constant lower temperature.

Mechanism of Testicular Cooling

In eutherian mammals with scrotal testes, the testicular venous blood in vessels running on the surface of the testis loses heat through the scrotal skin, and testis temperature falls to the same as the subcutaneous tissue. In the spermatic cord, the coiled spermatic artery—warm blood—runs among the multiple veins of the anterior pampiniform plexus—cool blood at the temperature of subcutaneous tissue. This arrangement acts as a counter-current heat exchanger (Waites, 1970) and results in a precooling of the arterial blood arriving to the testis. In marsupials, dolphins and seals there are analogous arrangements acting as heat exchanger (Setchell, 1998).

The key to the reduced temperature of the testis is the scrotal skin which in animals (rams, bulls, boars) is well supplied with apocrine sweat glands. In men, there are no eccrine sweat glands in the scrotal skin; but the water loss is much greater from this area than from sole or areola. The other important mechanism for controlling testis temperature is the tunica dartos muscle which is a layer of smooth muscle inserted into the skin in such a way that contraction of the muscle causes the scrotal skin to be thrown into folds. The dartos contracts in response to cold; under hot conditions, it relaxes, allowing the testis to move away from the body wall, and extending the scrotal surface area (Waites, 1970; Mieusset and Bujan, 1995). As a result, testicular temperature is lower than core body temperature and slightly higher than scrotal temperature in most mammals (Table 1) including men (Table 2).

Ways Used to Induce an Increase in Testicular Temperature

The effects of elevated temperatures on the testes have been studied in different ways: (1) translocation of the testis into the abdominal cavity: done in immature and adult animals, generally used for periods of days or weeks; (2) local heating of the testes by immersion in a water bath at various temperatures, on a single occasion or repeated; (3) whole body exposure to hot environments; (4) scrotal insulation. The two last-mentioned can either be continuous or intermittent, in order better to simulate the temperature fluctuations to which an animal would normally be exposed.

Among these different ways, the value of the achieved testicular temperature differentiates two types heating. In supraphysiological heating, the achieved testicular temperature is higher than the normal core body temperature. This heating is mainly used in rodents, with short exposures (30–90 min) requiring anesthesia—that suppresses scrotal thermo-regulative functions—and induces general

Table 1 Testis and rectal temperatures (°C) in conscious animals with scrotal testes

Species	Number of animals	Rectum	Testis	Rectum-testis difference	Authors

	11 (BD)	Cutaneous thermocouple	35.43 (± 0.25 SD)	35.92 (± 0.19 SD)

Values are means and ranges, or standard deviation (SD) or standard error of the mean (SEM); a = percentiles of individual readings: values (interquartile range); b = median value. (25th, 75th percentile); f = fecund; F = fertile; NR = not recorded. TATU = thermistor attached to the underwear (between the caudal poles of the testes). PM = postmen working 90 consecutive minutes in a standing position; BD = bus drivers driving (sitting) consecutively for 90 min. Measurements were done with men in supine position (except where indicated), but clothing, previous activities as well as room temperature and acclimatization were various.

changes—for example, the vascular flow—that are source of direct non-thermal testicular effects. In physiological heating, the achieved testicular values are never higher than body core temperature. Such a heating includes involve increased ambient temperature as well as induced cryptorchidism, or scrotal insulation; exposures are daily or repeated.

Effects of Exposure to Elevated Temperatures on the Testicles

Spermatogenesis

Pachytene and diplotene spermatocytes have been reported to be damaged in the testes exposed either to high increased temperatures in rats (43°C, 15 min), rams (40°C, 150 min) and mice (43°C, 15 min), or for continuous period of time in pigs (scrotal insulation, 100 h); the same germ cells were affected with experimental cryptorchidism in rats, rabbits, and mice, associated with a negative effect on round spermatids. Most of these affected germ cells undergo apoptosis; (Liu, 2010) but some of them escape to apoptosis, and this damage can extend to an effect on the development of preimplantation embryos. When the degree of heat exposure is more increased (by increasing the temperature or the time of exposure, e.g., cryptorchidism) other testis components are affected such as Sertoli cells and spermatogonia (Jégou et al., 1983; Setchell, 1998; Liu, 2010).

In humans submitted to different conditions increasing testicular temperatures, indirect data about germ cells were obtained based on both the three first constitutive phases of spermatogenesis: proliferation phase (Pp), meiosis phase (Mp) and spermiogenesis (Sg), and the epididymal transit (Et), which take place about 58–86 (Pp), 34–58 (Mp), 12–34 (Sg) and 0–12 days (Et) before ejaculation (Ahmad et al., 2012).

Whole body (fever)

Over a 16 months follow-up period in 27 men 15 reported at least one episode of fever (from 1 to 11 days; median 5; up to 40°C for 6 days). From the monthly delivered semen samples, the occurrence of fever had significant effect: sperm morphology and motility are adversely affected by a febrile episode during spermiogenesis. Sperm concentration was adversely affected by fever during the meiosis phase. These results are in line with previous studies dealing with fever either induced (40.5°C–41°C) or associated with diseases (Carlsen et al., 2003).

Scrotal exposure to high elevated temperature

Increasing scrotal temperature to 42°C by an electric lamp (30 min/day; 14–28 days) induced a drop in total sperm count (TSC) to 40%–70% of the initial TSC 3–11 weeks after heating, with a recovery to the initial TSC within 11–13 weeks after heating (Robinson et al., 1968). Using the timing of the different phases of spermatogenesis and Et, these data indicate a negative effect on sperm output during the first two phases, proliferation and meiosis.

Testes exposure to slight elevated temperature

A 2°C increase in testicular temperature was induced in 5 men by using underwear designed to push up and maintain the testes at the upper part of the root of the penis for 15 h/day (h/day) for 120 consecutive days. According to the chronology of spermatogenesis and Et, TSC was not affected by this heating when spermatozoa were stored in the epididymis when heating was induced. The major decrease in TSC at 34 days of heating suggests an active impact mainly on the meiosis phase from such a slight increase in testicular temperature. Furthermore, during heating, the first stage of spermatogenesis (mitosis and differentiation of spermatogonia) seems not to be affected, as has been reported in similar conditions of induced cryptorchidism in rats and rabbits (Ahmad et al., 2012).

Testicular volume

Following a single exposure of testicles in rats (41°C; 90 min; or 43°C; 30 min) or in mouse (43°C; 30 min), testes weight falls to almost half, reaching a minimum between 14 and 21 days afterwards, and then slowly returning to baseline values (Setchell, 1998). Results from these supraphysiological heatings differ from those of physiological heatings with no modifications in testes weight in boars submitted to whole body heating or in rats and mice under chronic ambient exposure (35°C and 33°C, respectively). In humans, a slight increase in testicular temperature (+2°C) every day (15 or 24 h/day; 12 months) induced a reversible reduction in testes weight of almost 50% for 24 h/day (Shafik 1991) of about 25% for 15 h/day.

Reproductive Hormones

Concerning the changes observed in circulating pituitary hormones, they are separated in time from the actual thermal stress; indicating these changes are unlikely to be caused directly by the heat exposure but may result from specific germ cell changes, either directly, or secondary to disruption of Sertoli or Leydig cells function (Jégou et al., 1984). Besides these delayed changes in circulating pituitary hormones, only few studies have experimented on the direct effects of temperature.

Elevated ambient temperature

When boars were exposed to 35°C (8 h/day; 90 min), there were slightly reduced testosterone (T) levels in blood on the 1st day of heating and after 7 and 14 days, with no significant differences thereafter. In rams exposed to an environmental temperature of 28°C–32°C (2 weeks), T concentrations were reduced in the testes and in blood from the spermatic internal vein. In bulls, exposure to an environment of 35°C (7 weeks) is associated with a fall in plasma T concentrations during the first 2 weeks followed by a return to control values during the rest of the exposure.

Scrotal heating

In boars subjected to scrotal insulation, plasma T levels decrease during the insulation period and return to normal afterwards. In rats, T concentration was not affected when measured in arterial blood at the end of a 30 min exposure of the scrota to temperatures of 33°C, 37°C, 41°C, and 43°C; but the response to LH and the amount of T in the testes after LH were severely repressed at the two high temperatures of 41°C and 43°C (Setchell, 1998).

Cryptorchidism and wet local heating

When spermatogenesis is arrested either by making the testes cryptorchid or by local heating of the scrotum using water bath, the T peripheral levels are not affected, but the concentrations of LH are increased.

Humans

A daily slight elevation in testes temperature (+2°C; 24 h/day) for a period as long as 12 months is without any effect on peripheral levels of FSH and LH; an observed reduction in peripheral T levels, to values still within normal range, was reversible within 3 months after the end of heating (Shafik, 1991). No significant modifications in reproductive hormones (FSH, LH, T and free T) were observed during the 30 follow-up weeks in 18 men whom scrota were submerged into a warm water bath (43°C; 30 min/day; six consecutive days; Wang et al., 2007); or during the 16 follow-up weeks in 20 men in whom the lower half body was soaked in a bathtub (43°C; 30 min/day; 10 consecutive days or once every 3 days, 10 times; Rao et al., 2015).

Effects of Exposure to Elevated Temperatures on the Epididymides

The epididymides, similar to the testes, are also maintained at a lower temperature than that of core body temperature: compared to the last one in conscious animals, temperature of cauda epididymis is 4°C lower in rats (Brooks, 1973), and those of caput and cauda epididymis 1.5°C and 1.1°C respectively lower in pigs (Stone, 1981). Epididymis subjection to body temperature was obtained by reflecting the epididymis to the abdomen (called cryptepididymis), while testes were kept in scrotal position. In rabbits, hamster and rats, cryptepididymis is associated with the reversible following consequences: (1) a rapid reduction in the cauda size, that is, a reduced capacity of sperm storage; (2) a major increase in the speed of transit of sperm, that is, a shorter epididymal transit time; (3) an inability of the cauda epididymis to maintain sperm viability; (4) changes in oxygen levels, water and ion transport mechanisms, proteins synthesis in cauda fluid (Bedford, 1994).

Moreover, epididymal sperm are susceptible to heat-induced DNA damage. In mice (42°C and 40°C; 30 min), a significant increase in the number of sperm with DNA damage was observed at the 24-h time point (Paul et al., 2008).

Effects of Exposure to Elevated Temperatures on Semen Parameters

It is usually reported that elevations in testis temperature (using whole body heating or scrotal heating) lead to reduced total sperm count (TSC) and decreased sperm motility while increasing the number of abnormal spermatozoa in bulls, rams, boars, pigs, stallions, and men.

While such effects are generally true, they results from both the value of the achieved temperature and the length of exposure to such an achieved value; for example, in animals: three groups of 4 rams were submitted to an identical regimen of scrotal insulation ($+2^{\circ}\text{C}$) for 8, 16, or 24 h/day. With scrotal insulation for 8 h/day, no significant effect on TSC appeared during the 162 consecutive days of insulation; however a slight depression of TSC was observed from day 100 for 16 h/day; and a fall in TSC started as soon as day 12 for a 24 h/day exposure (Mieusset et al., 1992); for example, in humans: a 1°C increase in scrotal temperature (20 h/day; 12 months) is without effects on sperm parameters while a 2°C daily increase in testicular temperature (15 h/day) induces in 3 months of exposure a 90% drop in TSC and a drastic reduction in the percentage of motile sperm (Soufir, 2017). In all experiments of a physiological induced increase in testis temperature in animals and humans, semen parameters recover their initial values within 1–2 spermatogenesis cycles after cessation of exposure depending of the length of exposure.

Effects of Exposure to Elevated Temperatures on Fertility

Male mice were exposed to elevated ambient temperature (32°C ; 24 h) then mated with females; fertilization rate, calculated from the ratio of cleaved ova to total ova recovered, fell from 79% between days 1–5 to 11% for days 16–20, and then recovered to 79% for days 26–30 after heat exposure. In male animals, infertility following exposure to heat has been known for a long time. The infertile period after heating the testes (rats: 43°C ; 30 min; mice: 42°C ; 30 min) lasted from between 7 and 14 days after heating to between 49 and 56 days (rats) and between 10 days and 38 days (mice). Such an infertile period has been reported in rams submitted to elevated ambient temperature or scrotal heating, the value of the achieved testicular temperature and the length of exposure defining the percentage of infertile male.

However, as exposure to heat induces a decrease in TSC and sperm motility, this infertility period could be explained by the reduced number of sperm being available to fertilize the oocytes. But when an equal number of motile swum-up sperm from scrotal-insulated and control rams were used for in vitro fertilization (IVF), the percentage of oocytes fertilized decreased from 73% to 7% with 16 h/day insulation for 18 days, and there were significant falls with 8 h/day insulation for 5 weeks, both during the insulation period and during the following 2 weeks (Setchell, 1998). These last results indicate that in such a situation of $a + 2^{\circ}\text{C}$ increase in testis temperature in rams, the reduced oocytes fertilization rate (1) is not only due to the number of sperm being available to fertilize the oocytes; (2) is linked to the daily length of exposure for the same achieved testicular temperature ($+2^{\circ}\text{C}$); (3) is reversible after cessation of exposure.

Effects of Exposure to Elevated Temperatures on Embryo Development

Embryonic death rate fell by 27% when rams were kept in air-conditioned chambers during the summer months. Ewes inseminated with frozen-thawed semen collected from rams on the 4th day of scrotal insulation ($+2^{\circ}\text{C}$; 16 h/day) showed a greater loss of embryos between day 17 and day 65 of pregnancy; as sperm used for insemination involve only sperm that were in the epididymis in the heating period (4th day), these data suggests that even epididymal sperm may be affected in such a way as to affect the developmental capacity of the embryos they produce (Mieusset et al., 1992; Mieusset, 1995). Such an epididymal effect may be observed in a previous study in which male mice were exposed to elevated ambient temperature (32°C ; 24 h); the ratio of implantation sites to fertilized ova was already less for the heated versus non-heated males in the first 5 days (71% vs. 90%; Setchell, 1998).

When normal female rats were mated to males whose testes had been heated (43°C ; 30 min), there were periods when litter size and the fetus to corpus luteum ratios were reduced, suggesting that there was significant mortality of the embryos. The sheep embryos produced by IVF, using semen from scrotal-insulated rams ($+2^{\circ}\text{C}$; 16 h/day) developed slightly less well than those obtained with control semen, and there was increased degeneration at the blastocyst stage. When the testes of male mice were heated (42°C ; 20 min) the animals remained fertile and litter size was not reduced, but the embryos they sired were about 25% smaller than controls at 10.5 days of gestation (Setchell, 1998). These findings of smaller fetuses with normal litter size from heat exposed sires have been confirmed for embryos at 14.5 days (Jannes et al., 1998).

Different studies looking at the effect of a single scrotal heating (36°C ; 24 h or 12 h) in mice have reported abnormal development in embryos recovered from females mated to heat-stressed males (36°C ; 24 h) including reduced number of embryos and blastomeres or impaired embryo development in IVF (Yaeram et al., 2006). The lower third of the body of mice was submerged in a water bath (38°C , 40°C or 42°C ; 30 min); paternal heat stress at 42°C resulted in reduced pregnancy rate, placental weight and litter size; abnormalities in embryonic development were detected at 3.5 days and IVF with sperm recovered 16 h or 23 days after scrotal stress at 42°C revealed a block in development between the 4-cell and blastocyst stages. By reporting DNA strand breaks present in spermatocytes recovered from testes subjected to 40°C or 42°C this study has provided evidence of temperature-dependent effects on germ cell DNA integrity and highlighted the importance of an intact paternal genome for normal embryo development (Paul et al., 2008).

Routes of Potential Exposure in Humans

Posture, Clothing and Activity

Scrotal temperatures (St) have been measured by different techniques in naked normal men in at least two of the following postures: supine, sitting with legs either together or apart, and standing. The lowest St observed was whilst standing, with

a mean lowering of from 0.3°C to 0.6°C when changing from supine to a standing posture. When sitting with legs together, St was higher than with legs apart, but in both sitting situations, St was higher than when standing. Being clothed elevates scrotal temperatures by 1.5°C–2°C when standing or supine, compared with an unclothed state (Jung et al., 2005; Mieusset et al., 2007).

Activity is associated with a lower St: when walking, scrotal temperature is 0.3°C–1°C lower than when sitting, independent of the type of clothing worn. Sleep is associated with the highest St, though values are lower when sleeping naked than when wearing pajamas or underwear (Jung et al., 2003).

Lifestyle Factors

Hot bath and sauna bathing are suspected sources of potential testicular heating. When St was monitored continuously with a miniaturized portable digital data recorder, it rose considerably in response to exogenous heat from the sauna, and reached core body temperature within 10 min of exposure (Jockenhövel et al., 1990). These data were confirmed in men submitted to two sauna sessions per week (15 min each; 80°C–90°C; 3 months); moreover sperm count and motility were reversibly decreased (Garolla et al., 2013).

Occupational Heat Exposure

Valid information was obtained from three case-control studies in which fertility status and/or semen analyses were compared between exposed and non-exposed workers to occupational heat stress: they reported (1) an increased odds ratio for occupational exposure to heat among men with sperm abnormalities; (2) a higher incidence of childlessness and of self-reported difficulty in conceiving; (3) a decline in the proportion of spermatozoa with normal forms (Mieusset and Bujan, 1995).

Driving or being seated is associated with an increase in St, alterations in semen parameters and longer time to pregnancy (Thonneau et al., 1997).

Clinical Factors

There are mainly two types of clinical factors (endogenous factors) that can be congenital or acquired.

Testicular mal descent (TMD)

Formerly called cryptorchidism, TMD is any testicle not within the scrotum at birth (congenital) or between 4 and 10 years old (acquired). When located in the inguinal canal (main TMD location), testis temperature is 1.5°C higher than the contralateral normally descended testis in impuberal boys. TMD treatment is a surgical positioning into the scrotum; in adult life, half these men will have still an elevated St associated with lower testicular volume, lower TSC and motile sperm than the other half in whom St has recovered normal value (Mieusset and Bujan, 1995).

Varicocele

Varicocele is a venous dilation of the spermatic cord, a factor associated with male infertility as its incidence ranges from 8% to 23% in the general or fertile versus 21%–39% in the infertile population. One of the suggested explanations for the pathophysiology of varicocele in male infertility is an increase in testicular temperature due to impaired heat transfer in the spermatic cord and/or decreased testicular blood flow. In men with varicocele, mean scrotal or testicular temperatures are significantly increased in uni- or bilateral varicocele compared with values in control men; and recovered after surgical treatment of the varicocele. However, the only way to prove the association of varicocele with increased St is to measure St in every infertile man with varicocele (Mieusset and Bujan, 1995).

Glossary

Endocrine disruptor “Is an exogenous substance or mixture that alters functions(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or in progeny, or (sub)populations” (WHO/IPCS, 2002).

Reproductive disruptor Is an exogenous substance or mixture that causes subfertility or infertility by interfering with normal functions of endocrine axes concerned with reproductive functions and their cross-talks, gonadal activities including gametogenesis, as well as postgonadal events associated with maturation, release, and fertilization of germ cells.

Abbreviations

ABP Androgen binding protein
AP-1 Activator protein 1
AR Androgen receptor
DMT1 Divalent metal transporter 1
EDCs Endocrine disrupting chemicals
EGF Epidermal growth factor
EGFR Epidermal growth factor receptor
FSH Follicle stimulating hormone
HIF1 Hypoxia-inducible factor 1
I κ B Inhibitor of kappa B
IUDs Intrauterine devices
LDH Lactate dehydrogenase
LH Luteinizing hormone
LPO Lipid peroxidation
MAPKs Mitogen activated protein kinases
NF- κ B Nuclear factor- κ B
NFAT Nuclear factor of activated T-cells
OS Oxidative stress
PI3K Phosphoinositide 3-kinase
PSA Prostate specific antigen
ROS Reactive oxygen species
ZIP, ZRT Iron regulated transporter (IRT)-like Protein

Introduction

The man-made changes to the environment vex the natural regulations altering the level of exposure of human to various essential and nonessential metals. Since last few decades, concern has been increasing about the possible deterioration of male reproductive health owing to various exogenous and endogenous flaws (Sengupta et al., 2017). Among the exogenous factors, the toxic consequences following pervasive exposure to metals stand at the top crosspiece (Sengupta, 2013a). The vulnerability of mammalian reproductive system to the adverse effects of metals is a threat to the power of procreation of the planet. Some metals are known to be beneficial to reproductive functions in men, involved in several reproductive processes, whereas environmental or occupational exposure to others are proven to disrupt male fertility. The male reproductive function usually be affected through the direct and indirect impacts of the toxic metals on the reproductive axis causing hormonal imbalance (pretesticular effect) leading to impaired sperm production in the testis, genomic constituents' alterations of the germ cells (testicular effect) as well as alterations of secretion of the accessory sex glands and disruption in sperm maturation at different levels (posttesticular effect) (Sengupta, 2013b). These propagations of metal toxicity are evoked by cellular macromolecules mediating intracellular catalytic, structural, and functional modulations. They may overcome the O₂ spin restriction donating a single electron, thus propelling free radical species which undergo uncontrolled destructive chain reactions causing oxidative damage to the cells. Furthermore, the suppressed activity of antioxidant enzymes, owing to metal toxicity, collapse body's own capability to combat and nullify such oxidative

damage. Other essential toxic effects of metals include DNA damage, impairment of cellular respiration, inhibition of several cell signaling pathways, etc. The mentioned impairments, individually or in combination by the toxic metals acting as “*reproductive disruptors*,” upset male fertility. As male reproductive system lack definite measurable cycle, these changes can be gauged by assessing testis size, semen quality, functioning of prostate and seminal vesicles, hormonal profile, tenacity of libido, and other basic parameters.

Major Sites of Action of Metals in Male Reproductive System

Exposure of men to metals is increasing with global advent, owing to their ubiquity in nature, wide use in industry, and long-term persistence in the environment. Metals may have direct effect on male reproductive system, targeting specific reproductive organs, or indirect effect, acting on the neuroendocrine system (Fig. 1).

These adverse effects can be irreversible if Sertoli cells are disrupted at the time of fetal development. The number of sperm generated in adulthood is determined by the number of Sertoli cells present, because each Sertoli cell can make provision for only a finite number of germ cells that mature into sperm. Proliferation of the Sertoli cells occurs during the fetal, neonatal as well as prepubertal period which predominantly sensitive to the hostile effects of metals. Disruption of spermatogenesis at any phase of cellular differentiation can reduce the total sperm count, heighten abnormal sperm numbers, and damage the stability of sperm chromatin. Metals may get accumulated in the prostate, epididymis, vesicular seminalis or seminal fluid, and thereby impair sperm motility. Metals can affect the male reproductive system indirectly leading to hormonal imbalance by disturbing the neuroendocrine system, and thus secretion of androgens from Leydig cells or Inhibin B, activins, and androgen binding protein (ABP) from Sertoli cells also get adversely altered. Oxidative stress (OS) is associated with the pathogenesis of male infertility and as human spermatozoa are particularly susceptible to OS, metals lead to propelling of an excessive reactive oxygen species (ROS) in the spermatozoa. This results in the lipid peroxidation (LPO) of the cell membrane. The decrease glutathione and other antioxidant levels, by exposure to metals, further contribute to the oxidative damage to spermatozoa even damaging its DNA. Destruction to the sperm membrane diminishes sperm's motility and capacity to fuse with the oocyte, while mutilation to the sperm DNA impede healthy paternal genomic influence to the embryo and escalates the risk of infertility, miscarriage, or any serious disease in the offspring. Exposure to “endocrine disrupting chemicals (EDCs)” may give rise to certain male reproductive malformations such as cryptorchidism, prostate cancer, hypospadias, and testicular are suspected to affect the endocrine system (Table 1).

Fig. 1 Major sites of metal action on male reproductive tract with their mode of actions. Through indirect effect metals disrupt endocrine regulations and by direct mechanisms they cause cellular toxicity and impairment of reproductive functions.

Table 1 Effects of metals on male reproductive system and their evaluation

Potential sites	Functions	Effects	Evaluative tests
Sertoli cells	Sertoli cells create the blood-testis barrier by the help of tight junctions. The luminal environment is regulated by FSH and inhibins These Sertoli cells: (1) nourish the developing germ cells; (2) remove the defective sperms; (3) secrete fluid aiding transport of sperm in the epididymis; and (4) release inhibins to control sperm production	↓ HPG-axis, ↓ spermatogenesis, abnormal spermiation, x CNS effects, testicular damage	Receptor analysis, hormone assay
Leydig cells	Secrete testosterone under the influence of LH. They are situated between the seminiferous tubules in the connective tissue		Receptor analysis, Radio-immuno assay (RIA); In vitro tests (co-culture), morphological analysis through staining procedures
Spermatogenesis	A chronological process, spans approximately 72 days in men. During this period, the immature undifferentiated spermatogonia grow into specialized spermatozoa. Spermatogonia go through several mitotic divisions to produce a large population of primary spermatocytes, which give rise to haploid spermatids by two meiotic cell divisions. The transformation of spermatids into elongated flagellar matured germ cells capable of motility is referred to as spermiogenesis. The release of finally formed mature germ cells is known as spermiation		Germ cell count and calculating the percentage of tubules without germ cells, spermatid counts and percentage of tubules with luminal sperm, germ cell culture, morphological analysis
Epididymis	Maturation of sperms (capacitation)		Histopathology, biochemical analysis
Seminal fluid	Regular sperm production		Spermatid counts, semen evaluation
Neuroendocrine system	Hypothalamo-pituitary axis, through LH and FSH, regulate the secretions of Leydig cells and Sertoli cells and thus impinging effects on spermatogenesis and every reproductive functioning of male		In vitro pituitary cell culture, hypothalamus perfusion, histopathology, hormone assay, RIA

Adversities and Benefits of Metals on Male Reproductive System

Metals With Adverse Effects

Arsenic

Arsenic is intensely found in the environment owing to anthropogenic and natural occurrence, such as contaminated drinking water. Its intrusion in male reproductive organ affects spermatogenesis adversely, reduces the organ weights among which testis and accessory sex glands are the most mentionable. Arsenic also causes reduction of serum luteinizing hormone (LH), follicle stimulating hormone (FSH), and testosterone. Its accumulation in testis, epididymis, and accessory sex glands attributes to decreased sperm count, motility, elevated abnormalities in sperm morphology, undesirable alterations in testicular enzyme activities, etc. It impinges the nocuous OS in the testicular tissues paving the way to testicular toxicity and lay deleterious impacts upon the hypothalamo-pituitary-gonadal (HPG) axis. It also causes DNA damage, germ cell deficiency, testosterone reduction, decreased sperm capacitation, and abnormal fertilization (Huang et al., 2016).

Bismuth

Men working in close proximity or in direct contact to bismuth and its compounds (such as bismuth oxychloride, bismuth subgallate, and bismuth subsalicylate), easily get inflicted by this metal. Bismuth tends to get accumulated in the lysosomes of the Leydig cells, in the testis and in the pituitary gland resulting in reduced activities of sperm creatine kinase owing to the displacement of its magnesium ions. The impairment of the Leydig cells also attributes to diminished testosterone production and thereby adversely afflicting the male reproduction.

Boron

Boron is absent in nature in elemental state but found in combination in borates, boric acid, borax, kernite, ulexite, colemanite, and borates. Boric acid is abundant in volcanic spring water. The global production of borates is as high as 2 million tons per year and mined mainly in the United States, Turkey, and Chile where the miners are the ones mostly affected by boron exposure. Boron, at low and high levels of exposure, inhibits spermiation, and epididymal sperm count respectively, thereby inducing testicular toxicity. It triggers the increase in weight, size and volume of the testis, and seminal vesicles. The testicular epithelium becomes disrupted

with very few spermatids owing to boron exposure. Moreover, spermatogonia is prompted to undergo apoptosis as can be perceived by the presence of their picnotic nuclei. Thus, boron has severe cytotoxic effects including distortion of seminiferous tubule epithelium, reduced spermiation, and hypertrophy of testis.

Cadmium

Cadmium may get access to human body via drinking water, ingested food, cigarette smoking or through inhaled air as well as dust or soil. Food crops harvested in polluted soil are the main contributors for inseminating the general population with cadmium. People are more susceptible to cadmium toxicity if they lack enough protein, calcium or iron in their body. Cadmium may interfere and impede sex hormone synthesis by acting as an EDC. High level of cadmium in blood mutilates the functioning of male reproductive system via distortion of sperm morphology, shrinkage of the testis, impairment of sperm motility, diminutions of semen volume, and decline in sperm count (Cheng et al., 2011). It is also worthy to know that this metal lays its detrimental effects on male prostate gland in the process of deregulating the level of PSA (prostate specific antigen) and morphological distortion of the gland. Its noxious effects on testicular vasculature may lead to testicular toxicity, necrosis and atrophy, damage to the germinal cells, decreasing the level of testosterone and also ravaging the accessory genital organs (Telisman et al., 2000). Owing to such far reaching damage to the reproductive organs, continuous exposure to cadmium can inculcate loss of libido and infertility in male.

Chromium

Drinking water, the ambient air, and food may expose human body to chromium or its compounds. Through any of the sources if chromium comes in contact with skin, it gets access to the body's internal environment. It is present in very low concentration in air (about $0.02 \mu\text{g m}^{-3}$) and water (< 2 ppb) in CrIII and CrVI forms. One may get exposed to chromium through wood preservative, household utensils, products used for cleaning, cement, tanned leather, and also several textiles. If we consider high level of exposure to chromium then we must focus on the workers in the industries using or processing chromium or its compounds. Both chromium III and VI are able to inflict adversities in spermatogenic process while the latter is reportedly more toxic. Hexavalent chromium (CrVI) is the widely used form of chromium in industries, and its exposure on male reproductive system may cause disturbed spermatogenesis, deteriorated semen quality, and reduced level of zinc and lactate dehydrogenase levels, all of which cumulate to impart male infertility. This may trigger OS and the following detrimental complications such as increased LPO in the testes leading to reduced sperm count and elevated sperm morphology distortions. Chromium is also capable of obstructing epididymal lumen thereby impeding the release of sperm.

Cobalt

Cobalt is an important oligoelement which is found in composition of vitamin B₁₂. Mainly beverages and foods convey cobalt to the body, several household products and cement being the other sources. The industries concerned with the use or production of various forms of cobalt such as those producing cobalt powder, using it to polish diamonds, processing cobalt alloy or preparing enamels and pigments, expose their workers to this metal. Though cobalt affects male reproductive system in a sluggish manner, in case of chronic exposure it intrudes into the normal functioning of male reproductive system thereby depressing sperm motility, testicular weight, and epididymal sperm concentration. Cobalt imposes indirect or direct repugnant effects on spermatogenesis and testosterone synthesis. Chronic exposure to cobalt may damage epididymal functioning to severe extent as the epididymis is the most susceptible organ to cobalt toxicity.

Fluoride

Human is vulnerable to fluoride exposure via toothpaste, soda, juices, fluoridated salts, and drinking water. Chronic to this metal develops structural and functional disorientation of the spermatozoa, debacle of spermatogenesis and disturbances in neuroendocrine control over reproductive functioning. Zinc deficiency, oxidative damage, and interference in signaling pathways prompted by fluorides lead to the mentioned damages to male reproductive components. Excess fluoride interferes with spermatogenesis by depressing levels of epidermal growth factor (EGF) and epidermal growth factor receptor (EGFR), modifying G-protein signaling, diminishing levels of testosterone, and its androgen receptor (AR). It also lays its impact upon thyroid hormone directly or indirectly hampering normal spermatogenesis.

Indium

High level of exposure to indium is most prominent among the workers in semiconductor or welding industries. It foists undesirable changes to male reproductive systems such as testicular epithelium vacuolization, distortions in sperm shape and reduction in sperm count, impaired libido and sexual behavior, decreased testicular and epididymal weights. It also reduces the activities of the sperm creatine kinase. Both indium arsenide and indium phosphide are able to inflict testicular toxicity, the former being more potent. Indium containing compounds also first adversely target the Sertoli cells instead of spermatogonia.

Lead

Lead is one of the leading metals triggering occupational health hazards as a wide proportion of industry workers and researchers deal with lead and their organs are exposed to its contamination. It is noxious to male reproductive system on account of reduced sperm parameters both qualitatively and quantitatively even at blood lead levels $< 150 \mu\text{g L}^{-1}$ (Jurasovic et al., 2004). Lead leads

to decline in semen volume, sperm count as well as sperm motility, while increased abnormalities in sperm head morphology, and also afflicts prostate secretions (Telisman et al., 2000). Treatment with lead chelators may reverse the complications inflicted by lead or it may also be reversed with time after cessation of regular exposure to lead. If paternal blood contains lead of approximately $300\text{--}400\text{ }\mu\text{g L}^{-1}$ then probability of spontaneous abortions is elevated, and also of the rate of live births (Lindbohm et al., 1991).

Mercury

At the level of its being toxic, mercury adversely affects the male fertility in both organic, and inorganic forms. The globulin levels in the serum which binds sex hormones and transports them to specific tissue locations show reduction in the workers exposed to mercury vapor. With increased mercury content in the paternal urine, the rate of spontaneous abortions increases. Testes are susceptible to both inorganic and methylmercury, the uptake and clearance of the latter being faster. This restrains normal spermatogenesis resulting in reduced sperm count and motility. It deforms testicular morphology and also depress DNA synthesis in spermatogonial stem cells. Cellular distortion of the Leydig cells and the seminiferous as well as reduced testosterone level in serum are the other established complications inflicted by mercury to pave the way to male infertility.

Molybdenum

Ingestion of industrial contaminant foods or even naturally occurring food and water may expose human to this metal. Elevated usage of molybdenum rich multiminerals/multivitamin supplements and occupational liabilities for workers of certain building materials, also lead to molybdenum exposure. The most distressing consequences owing to molybdenum exposure of male reproductive system are lack of libido, pronounced reduction in weight of testis and other vital reproductive organs such as epididymis, seminal vesicles and prostate glands, almost complete inhibition of spermatogenesis owing to severe histological damage to the testes especially to the germinal epithelium and interstitial cells. Accumulation of this metal to testis and other male reproductive organs may impose alterations in the activities of essential enzymes, such as it decreases sorbitol dehydrogenase (essential for sperm motility) activity and increases gamma-glutamyl transpeptidase (essential for spermatid maturation) and LDH (essential for energy metabolism of sperm) activities. Sperms, even if produced in reduced quantity, lack proper functional morphology following high molybdenum exposure.

Nickel

Nickel salts are regarded as industrial hazards to which human gets exposed through natural components. They perpetrate toxic progression in the peripheral tissues and also in the male reproductive tract. Nickel accumulation in testis may impose toxicity by various factors which are not yet specifically established. These effects are accentuated if its exposure gets coupled to protein deficiency in the male body. Increased nickel exposure is associated with decline in weight of essential male reproductive organs and activities of steroidogenic enzymes, impaired sperm morphology with sperm tail defects rendering them immotile or poorly motile. Nickel propels its toxicity via generation of free radicals leading to OS in the male reproductive tissues, evidenced through DNA damage, reduced total protein in testis, sperm count decrements, increase in the level of OS markers like LPO and induction of apoptosis in the testicular cells. The OS and the associated reproductive damage cumulate to impair male fertility. Besides being rigorously toxic, this metal also possesses some beneficial prospects to the male reproductive system since at low concentration it actually stimulates sperm motility, which is otherwise inhibited at high nickel concentration.

Silver

Silver is a precious metal which occurs naturally in the environment normally in the form of metal ore. In small quantity, it is regarded as beneficial to general health as it possesses certain antimicrobial capabilities. But in case of high level of exposure, silver is potent to reduce the activity of creatine kinase by displacing the Mg^{2+} from the enzyme thus impairing sperm energy homeostasis. Silver nanoparticles are able to percolate through the blood-testes barrier and get deposited in the testis where they can bind to the testicular tissues and induce generation of free radicals thereby initiating OS, toxicity and eventually cell death effects on sperm cells (McAuliffe and Perry, 2007).

Vanadium

Vanadium is an industrial hazard which inculcates its adverse effects on male reproductive system via ROS induced pathway which inflict toxicity in the germ cells bringing about reduced levels of gonadotropin and testosterone which in turn decline the sperm count. Gamma tubules are integral components of the microtubules which are vital for cell division thereby for spermatogenesis. Vanadium alters the structure of these gamma tubules poisoning inhibition to sperm production. Other indirect effects of vanadium on male reproductive system consists of hypertrophy of the adrenal gland causing increased secretion of glucocorticoids, elevated activities of the adrenal steroidogenic enzymes and consequently increased testicular LPO initiating damage to the cells.

Metals With Beneficial Effects

Gold

Gold is considered as one of the immensely precious and auspicious metals with enormous goodwill of having innumerable health benefits since ancient treatment regime. It is being utilized in "*Ayurveda*" for ailing several malaises, infertility of men being one. The

quantity of gold in human body is petite, and in semen, being < 1 mg mL may be detected (Jain et al., 2010). There is controversy regarding the source of gold in human body which may be the exposure to sea water or in vivo conversion of digested entities into gold. Although gold is hypothesized to lay ameliorating effects on male reproductive health, the beneficial effects of gold upon male reproductive is yet to be revealed with proper mechanisms.

Magnesium

Magnesium is vital for essential physiological processes and acts as cofactors for several enzymes in crucial energy metabolic pathways and biosynthesis of nucleic acid and proteins. Consumption of magnesium rich food and through hard water in various parts of the world are the sources through which magnesium get access inside the body. The observed consequences of intake of excess magnesium in the diet are enhancement of male fertility by improving the functions of testicular steroidogenic enzymes (Δ^5 3 β -HSD and 17 β -HSD) and testosterone level. It also improves other reproductive hormone levels (FSH and LH) in blood, and reduces OS in male gonadal system (Chandra et al., 2013). Magnesium is reported to improve sperm count in men and germ cell viability in male gonads.

Zinc

Zinc is essential for metabolic, morphologic as well as physiologic aspects of the male reproductive system. Zinc is omnipresent in serum and its constituents in considerable concentration. Its deficiency retards testicular development, degenerates tubular epithelium and decreases DNA, RNA, and protein contents of the vital reproductive organs. Zinc reportedly contributes to sperm count, motility, fertility capacity, and to improve the physical features of the sperm and the physical characteristics of sperm in infertile men (Hidioglou and Knipfel, 1984). Zinc can regulate male reproductive functioning via imposing stimulatory effects to pituitary gonadotropin and in turn testosterone by the activation of steroidogenic enzymes, while it is also linked with the—SH groups and disulfide linkages within the spermatozoa at the tail region. Zinc apparently regulates the contraction and the motility of sperm by controlling the energy utilization via adenosine triphosphate system and phospholipid energy reserves. Zinc is, thus, an imperative metal for customary agility of male reproductive organs and its deficiency is noxious to male fertility.

Metals With Dual Effects

Calcium

The trend of immense use of calcium supplementation through commercial food products, drugs, etc. are the heinous causatives for excessive exposure to calcium. Hard water contains calcium in abundance and drinking the same aids calcium access to the internal environment of body. Though calcium owns pivotal role in male reproductive functioning including different levels of sperm maturation, its detrimental effects on the same are also not under veils. Besides being a chemocastrative culprit, it is also considered to be a generator of free radicals promoting oxidative damage to the testicular germ cells, Leydig cells and interfere in the interactions of hypothalamus-pituitary-adrenal (HPA) and HPG axes. These, through a sequel of events, disrupt the normal spermatogenesis. Excess calcium exposure decreases weight of testis and accessory sex organs; reduces epididymal sperm count; declines activities of vital testicular enzymes such as Δ^5 3 β -hydroxy steroid dehydrogenase (HSD) and 17 β -hydroxy steroid dehydrogenase; diminishes serum levels of LH, FSH, and testosterone; and degenerative changes in the testicular histoarchitecture (Chandra et al., 2012).

Copper

Copper reaches the general population in abundance through innumerable sources of food, air, and water. This trace element is necessary for proper physiological functioning of the human body including fertility, but above a physiological limit it paves the way to eminent adverse implications including severe problems in the male reproductive system. As copper is an essential part of antioxidant enzymes, and involved in several redox reactions with iron, it improves male reproductive functions. But, people at close proximity to the smelters developing copper ore into metal are the ones mostly exposed to high range. Copper plumbing at homes also lead to significant exposure of this metal, owing to pipe corrosions emancipating copper into drinking water. Male reproductive system, when exposed to copper over prohibitive extent, is subjected to undergo distortion, and deregulations. It is severely detrimental to the spermatozoa mobility. It is able to bind to pituitary receptors ravaging LH regulations and to the FSH receptors to impede spermatogenesis. It interferes in oxidative process and reduces glucose consumption leading to immobility of spermatozoa and so, it is used for intrauterine devices (IUDs) in female whereas inflicts toxicity when used for male contraceptive purposes.

Iron

Iron is an essential element playing important role in male fertility. However, it can cause toxic effects when accumulating in large quantities. Anthropogenic sources of iron include steel industry, sewage, and mine-dust. Within the male reproductive system, Sertoli cell and Leydig cells are chief sources of ferritin. This protein acts as a readily accessible source of iron for developing sperm, while providing an extra layer to the testicular tissue. As an integral part of antioxidant enzymes, it protects germ cells from oxidative damage. It is also involved in cellular differentiation, proliferation, and metabolism. It is involved in several redox reactions in germ

cell, and thus energy metabolism and sperm motility. Iron deficiency anemia and thalassemia is known to be associated with male infertility, whereas iron overload causes testicular atrophy, morphological changes, impaired spermatogenesis, epididymal lesions, and impaired reproductive functions.

Manganese

Human body gets exposed to manganese through the ambient air where they occur naturally and also gets accumulated through mines and gasoline additives. It shows biphasic action on male reproductive system: being an integral part of antioxidant enzymes, it reduces OS in male reproductive system, while exposed in excess concentration, it disrupts reproductive functions. Manganese is considered essential to restore the oxidative balance in the sperms and neurons by impeding LPO generated by free radicals. It is an integral component of various enzymes involved in redox reactions while manganese itself acts as an oxidative chain breaker being able to quench peroxy radicals.

The clinical complications in the male reproductive system owing to the excess exposure to this metal may be reduced libido even impotency and the origin of manganese impacts are partly neurological. In case, manganese level exceeds the permitted level in blood, men can experience testicular tissue degenerations, reduction in testicular weight, sperm motility and sperm count, and also decline in serum levels of FSH and testosterone.

Selenium

Selenium is a vital trace element which is essential to maintain proper physiological functioning which also aid male reproductive operations such as antioxidant defense systems, immune function, and thyroid metabolism. Spermatogenesis and maintenance of semen quality are aided by two vital selenoproteins, phospholipid hydroperoxide glutathione peroxidase (PHGPx/GPx4), and selenoprotein-P, the former being the major one expressed by the testicular germ cells. Selenium deficiency leads to decline in sperm motility and sperm morphological distortions, including splintering at the mid-piece and abnormal shape of the sperm head. The antioxidant enzyme, glutathione peroxidase, contains selenium, and is inevitable for maintaining oxidative stability in the male reproductive cells.

The adverse effects of selenium dioxide on the testis and the observations such as oligospermia, intertubular edema, and degeneration of spermatids owing to chronic exposure to selenium, are the contrary effects of this otherwise beneficial metal. Moreover, in case of sustained high level exposure to selenium may be more detrimental as it can inhibit the testicular steroidogenic enzyme activities and markedly reduce the tubular areas, diameters and their perimeters obstructing sperm movement and ejaculation, thereby fostering male infertility (Boitani and Puglisi, 2008).

Mechanism of Action

Direct Effect

Metals interfere with the normal male reproductive functioning by thwarting the neuroendocrine regulation (pretesticular) or by acting directly upon the vital reproductive cells (testicular and posttesticular). In order to achieve access to the internal components, they must scout out the ways to enter the cells. In most of the cases, metals mimic essential endogenous ligands in order to bind to their receptors and in the process, they enter the respective cell to disorient the concerned signaling pathways resulting in reproductive disruption. For example, transferrin that transports iron may turn responsible for cellular toxicity by allowing excess iron as well as other metals which may mimic iron, like nickel, manganese, cobalt, copper, and zinc. Similarly, ZIP transporters may transfer some toxic metals, along with its patent ligand, zinc in excess. The phosphate/sulfate transporters aid the ingress of toxic metals which resemble phosphates and sulfates such as metal oxyanions, selenite, vanadate, and arsenate. Metals pave their way into the reproductive cells also by forming organic complexes, for example methylmercury may combine with cysteine to mimic methionine and with glutathione to mimic glutathione in order to use L-type neural amino acid carrier and glutathione carrier respectively. Lead mimics calcium to probe into the cells through the voltage-gated calcium channels.

While internalized, metals impede cellular signaling cascades within the male reproductive cells. Metals, such as arsenic, cadmium, chromium. Cobalt and nickel, targets the activation of ROS inducing oxidative damage to cytoplasmic components, lipid membrane as well as DNA and other cellular micromolecules. They also interfere MAPKs activities to bring about uncontrolled cell proliferation by inhibiting apoptosis. Arsenic, nickel, and copper are able to stimulate PI3K pathway to accelerate cellular growth induce HIF1 and thus establish a pseudohypoxia stimulating tumorigenesis, angiogenesis etc. They also lead to dislodging of I κ B from the NF- κ B resulting in unregulated activation of NF- κ B which in turn initiates carcinogenesis. The NFAT and AP-1 mediated signaling pathways may also get unnecessarily activated by the interfering metals leading to undesirable cellular differentiation, inflammatory responses and impaired repair process.

These cellular massacres by toxic metals increases cellular toxicity of reproductive cells. Leydig cells necrosis diminishes testosterone level which causes germ cell death and atrophy of secondary organs. In the Sertoli cells, the implications of metals distort cellular morphology and thus inhibit sperm development. Metal toxicity causes spermatogonial damage, perturbed growth, and death while damage to the spermatids' morphology give rise to abnormal sperms. The toxic progressions intervene

into the blood vessels supplying the testicles where endothelial necrosis lead to reduced blood flow thereby initiating oncotic necrosis and cellular apoptosis. In the epididymis and vas deferens, effects of metal insemination results in blockage, rupture of epithelial cells lining the lumen and formation of immotile sperm granulomes. Metals, if perpetuate inside the prostate and seminal vesicles, they adversely alter the intracellular mechanisms and curtail their secretions. Hence, the metals induct into the male reproductive cells, take up varied routes to ultimately establish a grievous toxic scenario and curb every vital male reproductive function (Fig. 2).

Fig. 2 The key routes of entry of toxic metals inside the reproductive cells and their mechanisms of action. Within these cells they disrupt various subcellular signaling pathways resulting in cellular toxicity that leads to various reproductive functional dysregulations.

Indirect Effect

The indirect effect of metals is mediated through the cross-talk among different endocrine axes. Most of the metals, following exposure, generate physiological stress and thus activate HPA axis to release the *stress hormone*, cortisol. Cortisol, through the cross-talk with HPG axis, restrains the secretion of LH and thus testosterone from Leydig cells (IPCS, 2002). Chronic exposure of toxic metals affects FSH release and impaired spermatogenesis. Activation of HPA axis is also concerned with generation of ROS and oxidative damage of gonadal cells. Some metals also impact on thyroid gland and disrupts hypothalamo-pituitary-thyroid (HPT)-HPG cross-talk to interfere the thyroid hormone mediated endocrine control of spermatogenesis (Rajender et al., 2011). By affecting the interplays among the different neuroendocrine axes with male gonadal system, toxic metals hinder normal endocrine control and spermatogenesis as well as sperm maturation to induce male infertility.

Anogenital Distance: A Marker of Steroidal Endocrine Disruption

Shanna H Swan, Icahn School of Medicine at Mount Sinai, New York, NY, United States
David M Kristensen, University of Copenhagen, Copenhagen, Denmark

Anogenital Distance: Definition and Brief History

Anogenital distance (AGD) is defined as the distance from the anus to the genitals. In rodents, the distance is defined by a single measurement, as the genital tubercle is a single point at birth. In human infants and adults, several genital landmarks have been used to measure AGD, with two measures used most frequently. In males, the shorter of the two most frequently used measures is the anoscrotal distance (anus to posterior insertion of scrotum) or AGD_{AS}, while the longer of the two measures, the anopenile distance (anus to anterior insertion of penis) or AGD_{AP} is, on average, twice as long as the anoscrotal distance in newborn male infants (see Fig. 1A). The corresponding measures in females are the anoclitoral distance (AGD_{AC}) and the anofourchette distance (AGD_{AF}) (Fig. 1B). This article will only discuss male AGD.

AGD has been used to identify offspring sex since 1912 (Jackson, 1912). It has been used as a marker of reproductive toxicity since 1996 when the United States Environmental Protection Agency (USEPA) identified AGD as an endpoint for animal-based reproductive toxicity assay (USEPA, 1996). The first studies of AGD in human populations suggested that AGD is under hormonal influence during fetal development (Salazar-Martinez et al., 2004), but it was not used as a measure of human reproductive toxicity until 2005 (Swan et al., 2005a).

Several measurement methods have been used in both infants and adults. One study compared the feasibility and reproducibility of adult male AGD measurements by two of the most commonly used methods ("lithotomy" or "frog-legged" position) (Mendiola et al., 2016). In this study men attending an outpatient clinic at a university hospital underwent an andrological examination at which AGD_{AS} and AGD_{AP} were measured in 70 men by these two methods. The overall agreement ($ICC \geq 0.80$) was similar and acceptable for both measures, and both methods were deemed adequate for epidemiological studies although the two methods differed systematically in their AGD measurements. Similarly, two methods have been used in measuring infant AGD. While no published study has systematically compared these methods in infants, unpublished data demonstrate that the coefficients of variation for the two methods are similar.

AGD and Body Size

Like all anatomical structures, AGD increases with age and body size. Because of the dependence of AGD's on body size, rodent studies frequently use an anogenital Index (AGI) (AGD divided by a function of body weight). Some human studies have also used AGI (Swan et al., 2005b; Loreto-Gomez et al., 2017) though most human studies have used the untransformed AGD measurement and included a term for body size (a function of weight or height) in multivariable models (Swan, 2008; Swan et al., 2015a).

Stability of AGD in Rodents and Humans

The stability of (body-size adjusted) AGD (referred to here as Adj-AGD) across the lifespan is an important issue. Data from multiple rodent studies indicate that (body-size adjusted) AGD is permanent. Several studies have examined the stability of

Fig. 1 Alternative measures of anogenital distance in males and female infants. From: Swan, S.H., Sathyanarayana, S., Barrett, E.S., Janssen, S., Liu, F., Nguyen, R.H.N., Redmon, J.B. and the TIDES Study Team. (2015). First trimester phthalate exposure and anogenital distance in newborns. *Human Reproduction*. **30**(4), 963–972.

Adj-AGD as rodents age and have found little change in Adj-AGD over time, although recent data (Kita et al., 2016) suggest that post-natal exposure to exogenous androgens and anti-androgens may alter this measurement. Body-size-adjusted AGD appears stable in humans, but to date there are no human populations in which AGD has been measured both in infancy and again in adulthood to confirm this. A recent unpublished analysis of The Infant Development and the Environment Study (TIDES) compared AGD in 281 boys at birth and 1-year of age and found that within-child measurements correlated significantly ($r = 0.56$ for AGD_{AS} and 0.51 for AGD_{AP}, $P < 0.0001$ for both). Further longitudinal follow-up is needed before concluding that Adj-AGD is stable over the lifespan.

Mechanisms of Action of Anti-Androgens on Male AGD

The term anti-androgen and AGD are closely entwined. The term “anti-androgen” is used to describe a class of compounds that oppose the action of steroidal androgenic hormones. The pharmacologic uses of anti-androgens began in the 1960s when these compounds were first prescribed to treat androgen-dependent conditions. It was not until the 1990s that the term was used to characterize an anthropogenic compound in the environment with endocrine action. In the same decade, studies performed in rats showed that the AGD is sensitive to anti-androgens, reflecting androgen action during fetal life (Gray et al., 1999). This research was followed by the discovery that AGD reflects fetal androgen exposure only within a specific “masculinization programming window” (Welsh et al., 2008).

Critical Developmental Windows for AGD in Rodents and Humans

The spectrum and severity of effects induced by EDCs are largely dependent on timing of exposure. Masculinization, a process driven by gonadal hormones at critical time windows in utero, is particularly sensitive to endocrine disruption. Androgen action during the MPW is essential for the differentiation of internal and external male genitalia and to ensure that reproductive tissues are responsive to subsequent hormonal stimuli (Welsh et al., 2008; Macleod et al., 2010). In rats, the MPW occurs during gestation days 15–18, whereas in humans it is believed to occur between weeks 8–14 (Welsh et al., 2008). Suboptimal androgen action during the MPW may result in short (feminized) anogenital distance (AGD) and several reproductive tract abnormalities, including abnormal development of sex accessory organs, micropenis, and hypospadias (Macleod et al., 2010; van den Driesche et al., 2011). Experimental manipulation of pre- and postnatal androgen environments in rodents suggests that adequate androgen exposure during the male programming window (MPW) is critical to achieving male-typical AGD length, although subsequent growth and development outside the MPW may require additional androgen exposure (Macleod et al., 2010; van den Driesche et al., 2011).

It is now evident that exposure to compounds that interfere with androgen action, including disruption of androgen production (e.g., dibutyl phthalate, ketoconazole, and acetaminophen) or androgen receptor signaling (flutamide) may result in abnormal male reproductive development if the exposure occurs during the MPW (embryonic days 15.5–19.5) in the rat. This is a time window that precedes morphological differentiation of the male tissues, where the androgens are not pivotal. Hence, it is only when blocking androgen action in the MPW that hypospadias and cryptorchidism and altered penile length in male rats can be induced, all of which are correlated with AGD.

In humans, the sexual dimorphism in AGD is evident by weeks 11–13 gestation increasing till week 17 and remaining approximately 50%–100% longer in males than in females (Fowler et al., 2011). To date, only one study in humans has examined the effect of varying exposure timing to identify the most sensitive period for AGD development. That study compared associations between maternal anti-androgen exposure (prenatal exposure to the phthalate diethylhexyl phthalate, DEHP, in three trimesters) and genital morphology (Martino-Andrade et al., 2016). Concentrations of DEHP metabolites in first trimester urine samples were inversely related to male AGD, while no appreciable associations were seen between AGD measures and any DEHP metabolite in the second and third trimesters. These data are consistent with the MPW for AGD development in rodent studies.

Clinical Correlates of Male AGD

Numerous rodent studies have reported associations between anti-androgen exposure and the joint occurrence of short AGD and impaired genital tract development (Foster, 2006; Ema et al., 2003). Congenital abnormalities of the genitalia (hypospadias, cryptorchidism) are, together with shortened male AGD, visible at birth, supporting the conclusion that these conditions reflect disruption of reproductive tract development during the fetal period (Dean and Sharpe, 2013). Several recent studies suggest that a short male AGD has implications for reproductive health in humans as well as rodents. Boys with genital defects (hypospadias and cryptorchidism) have significantly shorter AGD_{AS} than controls (Hsieh et al., 2012; Thankamony et al., 2013). In adult males, shorter AGD by either measure is associated with poorer semen quality and reduced testosterone and testicular volume (Eisenberg et al., 2012). In fact, short male AGD may be considered as one of several clinical markers of the Testicular Dysgenesis Syndrome (TDS) (Skakkebaek et al., 2001). While females are not the focus of this article, it is important to note that altered AGD may have implications for female. As well as male, reproductive development. Longer female AGD has been associated with conditions linked to increased androgenization in females such as congenital adrenal hyperplasia (Callegari et al., 1987) and multifollicular ovaries (Mendiola et al., 2012). In rodents, a shorter female AGD has been associated with reduced follicle counts in adulthood and

decreased fertility (Holm et al., 2016). AGD may therefore be an important biomarker of reproductive health in both males and females.

AGD as a Measure of Reproductive Toxicity

Brief Review of the Literature

At the turn of the 21st century, prenatal exposure to several phthalates, a class of environmentally pervasive industrial chemicals, was shown to cause a cluster of reproductive tract changes in male rodents. In 2000, Gray et al. showed that prenatal exposure to diethylhexyl phthalate (DEHP) and butyl benzyl phthalate (BBP) reduced male AGD by 30% (Gray et al., 2000). In 2006 Foster et al. reported that DEHP, BBP as well as dibutyl phthalate (DBP) produced a syndrome of male reproductive abnormalities that included demasculinization of the growth of the perineum resulting in a reduced anogenital distance (AGD) (Foster, 2006). Other changes included: malformations of the epididymis, vas deferens, seminal vesicles, prostate, external genitalia (hypospadias), cryptorchidism and testicular injury together with retention of nipples/areolae. The authors termed this cluster of endpoints the phthalate syndrome and noted that this syndrome had parallels with the human testicular dysgenesis syndrome (TDS). TDS was the term given to the cluster of interrelated male reproductive abnormalities in 2001 (Skakkebaek et al., 2001). While the phthalate syndrome and TDS are distinct, the former being defined in rodents, while the latter is defined in humans, short male AGD is now considered a component of both syndromes (Skakkebaek et al., 2016).

Because of the strong rodent data on the reproductive toxicity of phthalates and the ubiquitous exposure to phthalates, most human studies (10 studies) that have examined prenatal exposure to environmental chemicals have focused on phthalates (5 studies). However, studies showing associations between pre- and perinatal exposure to bisphenol A (BPA) (2 studies), DDE (2 studies) and dioxin (1 study) are available. In contrast, one study found that levels of the antiandrogen 1,1-dichloro-2,2-bis(*p*-chlorophenyl) ethylene (DDE) did not correlate with male infant AGD (Longnecker et al., 2007). These studies are summarized in Table 1. Here we provide a summary of results from the Study for Future Families (SFF), the study that initially reported associations between male AGD and prenatal exposure to an anti-androgen (phthalates) and the follow-up study that confirmed these associations; The Infant Development and the Environment Study (TIDES).

The Study for Future Families (SFF)

The Study for Future Families (SFF) examined AGD and other genital measurements in relation to prenatal phthalate exposure in humans. Standard measures of AGD (anopenile and anoscrotal) were obtained in 134 boys at 2–36 months of age as well as penile volume and degree of testicular descent. AGD was significantly correlated with penile volume ($R = 0.27$, $P = 0.001$) and the proportion of boys with incomplete testicular descent ($R = 0.20$, $P = 0.02$). This initial publication from SFF used anogenital index (AGI), defined as AGD divided by weight at examination [$AGI = AGD/\text{weight (mm/kg)}$] to examine age-adjusted AGI in relation to phthalate metabolite concentration in prenatal urine samples (median week 27 gestation in regression and categorical analyses that included all data available in 2005 ($n = 85$) (Swan et al., 2005b). The study reported that urinary concentrations of four phthalate metabolites [monoethyl phthalate (MEP), mono-*n*-butyl phthalate (MBP), monobenzyl phthalate (MBzP), and monoisobutyl phthalate (MiBP)] were inversely related to AGI. This study also examined a phthalate mixture using a summary phthalate score and the age-adjusted AGI decreased significantly with increasing phthalate score (p -value for slope = 0.009). This initial publication was followed by a second publication which included a larger data set and control of AGD for infant body size in regression analyses, rather than by using AGI (Swan, 2008). This second publication looking at AGD and prenatal phthalate exposure in SFF included 106 boys, 68 with two AGD measurements. Mixed models were used to include multiple measurements per child and body size was controlled by including a term for weight percentile (weight-for-age based on was determined by sex-specific estimates of weight percentiles in the US population (<http://www.cdc.gov/growthcharts/>). All metabolites of diethylhexyl phthalate (DEHP), diethyl phthalate (DEP) and dibutyl phthalate (DBP) were significantly associated with shorter AGD, as was the summary phthalate score. For all metabolites, an interquartile increase in concentration was associated with a 3%–5% shorter AGD.

The Infant Development and the Environment Study (TIDES)

The Infant Development and the Environment Study (TIDES), which recruited women in their first trimester of pregnancy in four US cities in 2010–2012, was designed as a follow-up to SFF and included larger sample size ($N = 366$ boys), phthalate measurement in urine from all three trimesters and AGD measurements in boys at birth and 1 year of age. In this population, concentration of DEHP metabolites were significantly reduced relative to those in SFF women, in whom phthalates were measured 10 years earlier. Despite these lower exposure levels, three metabolites of DEHP were significantly and inversely associated with both measures of boys' AGD. Associations (b, 95% confidence interval (CI)) between AGD_{AS} and (log₁₀) SpG-adjusted phthalate concentrations were: -21.12 (-22.16 , -20.07) for mono-2-ethylhexyl phthalate (MEHP), -21.43 , (-22.49 , -20.38) for mono-2-ethyl-5-oxohexyl phthalate (MEOHP) and -21.28 (-22.29 , -20.27) for mono-2-ethyl-5-hydroxyhexyl (MEHHP). Associations were of similar magnitude for AGD_{AP} (Swan et al., 2015a). No other phthalate metabolites were associated with any genital measurement in boys nor were phthalate metabolites associated with either AGD measure in girls. These phthalate-AGD associations were significant only for exposure in the first trimester, consistent with rodent data on the male programming window (Martino-Andrade et al., 2016).

Table 1 Male AGD and perinatal exposure to EDCs

<i>First author (year) country [citation]</i>	<i>Exposure(s)</i>	<i>Age at AGD assessment</i>	<i>Results (N for AGD/EDC associations)</i>	<i>Time of sample collection time (sample medium)</i>
Swan et al. (2005b)	DEHP, DBP, DEP, other and phthalates summary of phthalate exposure	9–27 months	MBP, MiBP, MBzP, MEP and summary phthalate score significantly and inversely associated with AGI (ano-penile AGD/weight) ($N = 85$)	Median 27 weeks (urine)
Longnecker et al. (2007)	DDE	Birth	DDE not associated with any AGD measure ($N = 781$)	Postpartum (serum)
Swan (2008)	DEHP, DBP, DEP, other phthalates and summary of phthalate exposure	9–27 months	DEHP, DBP, and DEP metabolites and summary phthalate score associated with shorter (ano-penile) AGD; ($N = 106$, 68 with two measurements)	Median 27 weeks (urine)
Torres-Sanchez et al. (2008)	DDT and DDE	3,6, 12, or 18 months	DDE (not DDT) in first trimester samples associated with shorter API (ano-scrotal AGD/coccyx-scrotal distance) ($N = 37$)	Three trimesters (serum)
Suzuki et al. (2012)	DEHP (MEHP), other phthalates	Birth	MEHP sig. associated with shorter (ano-penile) AGD/weight; other phthalates not associated ($N = 111$)	Mean 29 weeks (urine)
Miao et al. (2011)	BPA	0–17 years	Maternal occupational BPA exposure associated with shorter (ano-penile) AGD ($N = 153$)	Prenatal (air)
Bustamante-Montes et al. (2013)	Summary of phthalate exposure	Birth	Phthalate index in first trimester associated with shorter AGD (ano-penile); individual phthalates not associated ($N = 73$)	Each trimester (urine)
Vafeiadi et al. (2013)	Dioxins (dioxin-like activity)	Birth or mean 16 months	Dioxin associated with shorter AGD (ano-penile) ($N = 119$)	Postpartum (serum)
Swan et al. (2015b)	DEHP, other phthalates	Birth and 1 year	DEHP metabolites in first trimester associated with shorter AGD (both anopenile and anoscrotal); other phthalates not associated ($N = 366$)	Each trimester (urine)
Bornehag et al. (2015)	DINP, DEHP, other phthalates	3 years	DINP metabolites associated with shorted AGD (anoscrotal); other phthalates not associated ($N = 196$)	First trimester (urine)
Liu et al. (2014)	BPA	Birth	BPA not associated with AGD ($N = 137$)	Late third trimester (urine)

Most studies prior to TIDES examined AGD and prenatal EDC exposure collected samples in late pregnancy, except one other study that collected samples in the first trimester (Bornehag et al., 2015) and one which collected samples in the second trimester (Huang et al., 2008). In TIDES, all birth exam measurements (including weight and length) were measured with standardized equipment and protocols and timed to minimize variability.

Conclusions

Anogenital distance (AGD), an easily measured sexually dimorphic measurement reflecting the androgenicity of the early fetal environment has been used for over 100 years to sex newborn pups and as a measure of reproductive toxicity in rodent studies. While no epidemiological study had used this measure prior to 2004 (Salazar-Martinez et al., 2004), since that time 42 studies on human AGD have been listed in PubMed, most of these (59.5%) since 2011. These studies document the feasibility of obtaining reliable AGD measurements in infants, children and adults of both sexes. Several factors have been reported to alter infant AGD and it has been shown to have important clinical correlates. The available literature on human AGD and prenatal exposure to endocrine disrupting chemicals demonstrates the value of this measurement in human, as well as non-human toxicology. As additional studies undertake these measurements it will be possible to generate populations norms, which may be useful in clinical settings as well as epidemiological studies.

Glossary

Androgen Steroid molecule responsible for male characteristics.

Androgen receptor Intranuclear protein that, when activated by androgens, will initiate the transcription of selected genes.

Anogenital distance The distance from the anus to the genitalia, which is a marker of exposure to androgens during fetal life. The anogenital distance is longer in males than in females.

Cryptorchidism Undescended or incompletely descended testis.

Endocrine disruptive compound An exogenous substance or mixture that alters function(s) of the endocrine system.

FSH A hormone synthesized in the pituitary gland that regulates the development, growth, pubertal maturation, and reproductive processes of the body.

Gonadotropins Hormones secreted by the anterior pituitary of vertebrates and regulating normal growth, sexual development, and reproductive function.

Hypospadias Congenital anomaly characterized by failure of the urethra to form completely.

LH A hormone synthesized by the pituitary gland that stimulates Leydig cell production of testosterone.

Testosterone An androgen produced by the interstitial Leydig cell in the testis.

Xenobiotic A chemical compound that is foreign to a living organism.

PBDE Polybrominated diphenyl ether

PFAS Perfluoroalkylated substance

PPAR Peroxisome proliferator-activated receptor

StAR Steroidogenic acute regulatory protein

TDS Testicular dysgenesis syndrome

Definition

In the early 2000s, the documented increase in male reproductive disorders, should they be developmental (cryptorchidism, hypospadias), pubertal (delayed puberty, gynecomastia), or related to the adult testicular function (declining sperm quality, subfertility, testicular cancer), was theorized to be part of a common disorder named testicular dysgenesis syndrome (TDS). Conceptualized by Skakkebaek et al. (2001), the TDS hypothesis identifies adverse environmental factors acting upon a susceptible genetic background to disrupt embryonal programming and gonadal development during fetal life. Environmental factors acting as endocrine disrupting compounds (EDCs) have since then been identified as part of the TDS etiology.

When the field of endocrine disruption first emerged in the late 1960s, investigation was largely focused on environmental chemicals displaying estrogenic properties. The term antiandrogenic was used for the first time in 1994 to describe the properties of the pesticide vinclozolin. Since then, numerous compounds and/or their metabolites have been identified as antiandrogens (Table 1), herein defined as any class of xenobiotic that opposes the action of androgens by either altering androgen production, acting as an androgen receptor (AR) antagonist, or a combination of these different modes of action. An extensive body of literature now associates exposure to such compounds to antigonadotropic effects at large, including adverse effects on masculinization, morphological development of the urogenital system, secondary sex characteristics establishment, and adult testicular function.

Steroidogenesis Inhibitors

Androgens derive from cholesterol, either synthesized endogenously from acetyl-CoA or imported from exogenous sources by receptor-mediated uptake of low and high-density lipoproteins. In steroidogenic cells, cholesterol is first transported from the cytoplasm to the mitochondria under the regulation of the steroidogenic acute regulatory protein (StAR). The biosynthesis of androgens then requires a battery of oxidative enzymes to convert cholesterol, first to pregnenolone in the mitochondria, and then to various precursors leading to testosterone in the smooth endoplasmic reticulum near here. Two major families of enzymes are at play: the cytochrome P450 superfamily (i.e., CYP11A1, CYP17A1, CYP21), and the steroid dehydrogenase family (i.e., HSDB3, HSD17B3). Several environmental pollutants, among which industrial chemicals and pharmaceuticals, have been shown to exert antiandrogenic effects by acting as steroidogenic enzymes inhibitors.

Industrial Chemicals

Plasticizers

Phthalates are used as plastic emollients, matrices, solvents, and excipients in industrial applications. They are used in the production of a wide range of consumer products, including construction materials, toys, packaging films and sheets, medical tubing and blood storage bags. Because they are not covalently bound to their supports, phthalates leach out to the environment and have become ubiquitous environmental contaminants, with numerous studies reporting widespread human exposure through oral, inhalational, dermal, and parenteral routes. The most commonly studied antiandrogenic phthalates include di(2-ethylhexyl) phthalate (DEHP) and di-*n*-butyl phthalate (DBP).

Gestational exposure to phthalic acid esters in murine models produces a unique combination of phenotypes in the male offspring sometimes labeled “phthalate syndrome” that includes—depending on the window and dose of exposure—hypospadias, cryptorchidism, decreased anogenital distance, retained nipples, and epididymal and accessory glands agenesis. Histologically, in utero exposure to phthalates can translate postnatally into the presence of multinucleated gonocytes or testicular hemorrhage. At adult age, these disorders have been shown to result in impaired testosterone and sperm production. Such effects are corroborated by epidemiological studies showing associations between levels of phthalate metabolites in body fluids and reproductive

Table 1 Main environmental antiandrogens and their known mechanisms of action^a

^aClassification was established based on the available literature.

development and function disorders, such as decreased anogenital distance and higher incidence of gynecomastia in boys, or decreased testosterone and semen quality in men (Albert and Jégou, 2014). Proposed mechanisms of action for the antiandrogenic effects of phthalate include an impairment of steroidogenic enzyme gene expression (among which StAR, CYP11A1, CYP17A1, HSD3B) or a dysregulation of the peroxisome proliferator-activated receptor (PPAR) pathway.

Bisphenol A (A2,2-bis (4-hydroxyphenol) propane or BPA) is another synthetic compound used primarily in the manufacture of polycarbonate plastic and epoxy resins, and as an antioxidant or inhibitor of polymerization additive to other plastics. Sources of human exposure to BPA include food contamination, dermal exposure, and inhalation of indoor dust.

While BPA was originally known for its estrogenic activity, it is also considered to be a weak antiandrogen because of its affinity for AR and its ability to inhibit steroidogenic enzymes, such as HSD3B, CYP17A1, or HSD17B3. In rodent models, the effects of in utero exposure to BPA are still controversial, with some studies only showing decreased anogenital distance and plasma testosterone levels in male pups. However, in vitro organotypic cultures using mouse, rat, and human fetal testes showed decreased testosterone production after exposure to BPA. Intrauterine exposure to BPA also possibly induces a range of effects in the adult testis, including decreased sperm counts, DNA damage, and reduced sperm motility (Peretz et al., 2014). These effects are maintained in subsequent generations, suggesting an epigenetic reprogramming of germ cells by mechanisms that persists well beyond the initial exposure. These antiandrogenic reproductive effects are corroborated by epidemiological studies reporting associations between BPA exposure during fetal life and masculinization defects, such as shorter anogenital distance or hypospadias. In men, exposure to BPA is associated with reduced sperm quality, decreased sex hormone levels, and sexual function impairment. In applying the precautionary principle, several countries have restricted or banned the use of BPA in food contact products, especially for small children.

With increasing concern from the scientific community and emerging governmental regulations, the chemical industry substituted some of these plasticizers on the market. In some products, BPA was thus replaced by compounds such as bisphenol F or bisphenol S, while DEHP was replaced by 1,2-cyclohexane dicarboxylic acid diisononyl ester (DINCH). Recent studies however suggest that these replacements are bioactive in different settings, and may exert hazardous effects as well, although deemed safe by classical toxicology regulatory standards (Sartain and Hunt, 2016).

Surfactants

Perfluoroalkylated substances (PFASs) are synthetic organofluorine compounds with high stability and low surface tension. Insoluble in water and organic solvents, they repel water, dirt, and oils, and are used as surfactants in a wide range of products such as food packaging, paints, textiles, footwear, furniture, carpets, lubricants, waxes, and fire-fighting foam for oil fires. Human exposure occurs through food, water, and inhalation of domestic dusts contaminated with PFASs used as surfactants for impregnation of consumer goods; children crawling and playing on floors are therefore particularly exposed. Due to their hydrophobic and lipophobic properties, PFASs are readily absorbed and bind to proteins in blood serum and accumulate mainly in organs such as liver, kidney, and spleen, but also in testes and brain.

Carcinogenic in animal models, PFASs also display endocrine disruptive properties. Exposure of adult male rats to certain PFASs results in a decrease in testosterone production and steroidogenic gene expression, as well as Leydig cell hyperplasia and adenomas (Jensen and Leffers, 2008). In men, the overall evidence concerning PFAS exposure and sperm quality or androgen levels remains inconsistent, and necessitates further studies.

Pharmaceuticals

Mild Analgesics

Acetaminophen, aspirin, ibuprofen, and indomethacin are among the most commonly used over-the-counter painkillers. Due to their wide use for self-medication and prophylactic purposes, some mild analgesics are also found in wastewaters. Several independent epidemiological studies found significant associations between the intake of acetaminophen alone or in combination with nonsteroidal anti-inflammatory drugs during pregnancy and an increased risk of cryptorchidism in newborn boys. Ibuprofen consumption during pregnancy was also associated with an increased prevalence of hypospadias in male infants.

These observations lead to investigations in murine models, in which intrauterine exposure to indomethacin, acetaminophen, and aspirin reduced anogenital distance in the male offspring; the latter two also significantly reduced intratesticular testosterone levels. Direct evidence that acetaminophen, aspirin, indomethacin, and ibuprofen display antiandrogenic properties was also provided using ex vivo organotypic culture of rat fetal, human fetal, and human adult testes (Kristensen et al., 2016), although extremely sensitive to dosage and windows of exposure. The precise mechanisms underlying the antiandrogenic action of mild analgesics are still unknown; one proposed mechanism involves the inhibition of steroidogenic enzyme gene expression, such as CYP17A1.

Androgen Receptor Antagonists

During fetal and early life, androgens are responsible for the differentiation, growth, and development of the male urogenital system, accessory sex glands, and external genitalia. After this initial action, the testis remains quiescent until puberty, when gonadal

activity increases under the control of gonadotropins. Acting in multiple primary loci, the elevated circulating levels of androgens, both testosterone and 5 alpha-dihydrotestosterone (5 alpha-DHT), are then responsible for the establishment of secondary sex characteristics and the initiation of spermatogenesis.

Androgen action is mediated through the androgen receptor, a member of the nuclear receptor superfamily with specified structural domains that define their molecular actions as ligand-inducible transcription factors (Fig. 1). In target cells, androgens diffuse passively into the cytoplasm and bind to the AR forming dimers in response. This binding is hypothesized to result in a conformational change exposing the receptor's DNA-binding domain and enabling it to bind to androgen response elements (AREs) on the nuclear chromatin, thus initiating gene transcription.

Fig. 1 Targeted effects of environmental antiandrogens. *AL*, aldrin; *AR*, androgen receptor; *ARE*, androgen responsive element; *BPA*, bisphenol A; *DDT*, dichlorodiphenyltrichloroethane; *DIEL*, dieldrin; *LDN*, lindane; *LNR*, linuron; *MA*, mild analgesics; *MTX*, methoxychlor; *PBDE*, polybrominated diphenyl ether; *PCL*, prochloraz; *PCM*, procymidone; *PHT*, phthalates; *SER*, smooth endoplasmic reticulum; *VCZ*, vinclozolin.

Several environmental antiandrogens adversely affect the male reproductive development and function by acting as AR antagonists. These compounds bind to the AR with moderate affinity and induce a conformation that either fails to protect the AR against degradation, is incompatible with AR dimerization, or prevents binding to the AREs, resulting in impaired transcriptional activation. Among them are agrochemicals and industrial additives.

Agrochemicals

Fungicides

Vinclozolin and procymidone are dicarboximide fungicides used to control diseases, such as blights, rots and molds in vineyards and on certain fruits and vegetables. Workers can be exposed to them during handler activities such as mixing, loading, applying and flagging, or by re-entering treated sites. Exposure to vinclozolin and procymidone can also occur non occupationally to golfers playing on treated golf courses and homeowners coming into contact with sod which has been previously treated on a sod farm, or through residues in food and water.

Vinclozolin and its two primary metabolites, 2-[[[(3,5-dichlorophenyl)-carbamoyl] oxy]-2-methyl-3-butenic acid (M1) and 3',5'-dichloro-2-hydroxy-2-methylbut-3-enamide (M2), competitively bind to AR (Fang et al., 2003) and inhibit DHT-induced transcriptional activation by blocking AR binding to AREs. Procymidone, on the contrary, exhibits almost identical affinity for the AR than the antiandrogenic drug flutamide, while its metabolites exhibit varying but lower levels of affinity. When administered during sexual development in a murine model, vinclozolin and procymidone produce an undervirilization and feminization of male pups, attested by a reduction in anogenital distance, retained nipples, hypospadias, a blind vaginal pouch, reduced to absent accessory glands, and a delay in pubertal maturation; such malformations lead to a greater rate of infertility at adult age (Gray et al., 2006). Vinclozolin has also been shown to promote transgenerational inheritance of reduced male fertility: after a transient embryonic exposure at a critical time during gonadal sex determination, an adult testis phenotype of decreased spermatogenic capacity and male infertility was found to be transgenerational, and appeared to be associated with altered primordial germ cell epigenetic programming via noncoding RNAs and alterations in gene expression. In spite of these concordant data in laboratory models, no epidemiological study has specifically looked into the antiandrogenic effects of vinclozolin or procymidone in men. Both vinclozolin and procymidone have now been phased-out for most domestic food uses.

The imidazole fungicide prochloraz was introduced in the late 1970s for horticulture and agriculture purposes in Europe, Asia, Australia, and South America. It is still currently in use on wheat, barley, mushrooms, cherries, turf on golf courses, and in flower production. The action of imidazoles used as fungicides or antimycotic drugs (e.g., ketoconazole) is based on the inhibition of the cytochrome P450-dependent 14 α -demethylase activity required in the conversion of lanosterol to ergosterol, an essential component of fungal cell membranes. The molecular basis of this inhibition is the presence of an imidazole moiety that interacts strongly with the iron atom of cytochrome P450. However, this binding is fairly unspecific, and prochloraz also inhibits the activities of a broad spectrum of other cytochrome P450-dependent enzymes, including key enzymes involved in steroidogenesis such as CYP17A1. Prochloraz is also an AR antagonist, and even though in vitro studies suggest that its dominant mechanism of action is the inhibition of testosterone production, its AR antagonistic properties are likely to be magnified by decreased circulating testosterone levels.

In murine models, gestational exposure to prochloraz produces a significant decrease in testosterone levels in male fetuses and smaller anogenital distance, nipple retention, and hypospadias in the male offspring (Vinggaard et al., 2006). Peripubertal exposure to prochloraz also delays pubertal development. A brief exposure at adult age does not significantly affect the adult male reproductive function. As of today, there are no epidemiological studies available on the effects of prochloraz in men reproductive function.

Insecticides

Dichlorodiphenyltrichloroethane (DDT) is an organochlorine. Originally used to control malaria and typhus among civilians and troops, DDT was increasingly used as an agricultural insecticide after World War II. This widespread use was famously condemned by Rachel Carson in her 1962 book *Silent Spring*, where she cataloged environmental impacts that coincided with the use of DDT in the United States, revealing its threat to wildlife and human health. The publication triggered a large public outcry, followed by an environmental movement, that eventually lead to a global ban of the use of DDT for disease control in more than 170 countries. In 1995, DDT was listed as a persistent organic pollutant by the Stockholm Convention. Since 2004, the use of DDT is legally limited to vector control, but agricultural use is possibly sustained in countries such as India or North Korea.

The main DDT isomer, *p,p'*-DDT, as well as its two primary metabolites *p,p'*-dichlorodiphenyldichloroethylene (*p,p'*-DDE) and *p,p'*-dichlorodiphenyldichloroethane (*p,p'*-DDD), are persistent organic pollutants, bioaccumulate in fat tissues and biomagnify up the food chain, causing them to be detected in human tissues despite the ban. *p,p'*-DDE is a potent AR antagonist and inhibits the response to FSH (follicle stimulating hormone) and androgen-dependent gene expression in vitro. When administered during gestation in the rat, *p,p'*-DDE reduces anogenital distance, induces nipple retention, and permanently reduces androgen-dependent organ weights, but does not increase the incidence of hypospadias. Exposure during puberty produces a delay in preputial-separation. In adult male rats, exposure to DDT alters testosterone production, produces a dose-dependent reduction of testicular and seminal vesicle weights, and reduces the number and proportion of motile spermatozoa in cauda epididymides (Gray et al., 2006; Wilson et al., 2008).

Epidemiological studies investigating the effects of in utero exposure to DDT and *p,p'*-DDE remain inconclusive as to whether environmental exposure levels significantly decrease anogenital distance or increase the risk of hypospadias and cryptorchidism in newborn boys. The effects of DDT in adult men are also very much debated, with studies showing negative associations between levels of DDT and *p,p'*-DDE in body fluids and reproductive hormone levels, semen volume, sperm count, motility, morphology, and chromatin quality, while others show no such association. A few studies also identified positive associations between *p,p'*-DDE exposure and sperm concentration, reinforcing the need for further investigation.

Methoxychlor, a synthetic organochlorine, was initially intended to be a replacement for DDT. More rapidly metabolized and excreted in mammals, it is less acutely toxic than DDT and more readily biodegraded. Methoxychlor is used against a wide range of pests encountered in agriculture, households, and ornamental plantings. Despite a ban in the United States and Europe, methoxychlor is still used in several countries, and still detected in human urines, blood, cord blood, and follicular fluid.

Methoxychlor can be metabolized by the liver into two demethylated compounds, (2,2-bis-(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE) and 2,2-bis-(*p*-hydroxyphenyl)-1,1,1-dichloroethane (HPDE), and two 0-ring methylated compounds. Each of these metabolites have been demonstrated to act differentially on the estrogen and androgen receptors. Both methoxychlor and HPTE are AR antagonists (Fang et al., 2003) and inhibit steroidogenic enzymes such as CYP11A1, HSD3B, and HSD17B3. Methoxychlor alters testosterone production both in vitro and in vivo. In male murine models, exposure to methoxychlor results in a pubertal delay, as well as reduced growth, seminal vesicle weight, cauda epididymis weight, and caudal sperm count. However, epidemiological studies in humans remain scarce.

Other DDT replacements from the 1940s include aldrin and dieldrin. Aldrin is a chlorinated insecticide used against soil-dwelling pests, for wood protection and, in the case of dieldrin, against insects of public health importance. The two compounds are closely related with respect to their toxicology and mode of action. Aldrin is rapidly converted to dieldrin under most environmental conditions and in the body. Dieldrin is a highly persistent organochlorine compound that has low mobility in soil, can be lost to the atmosphere and bioaccumulates. Since the early 1970s, a number of countries have either severely restricted or banned the use of both compounds, particularly in agriculture, and since 1995, they are both listed as persistent organic pollutants by the Stockholm Convention.

Both aldrin and dieldrin are AR antagonists. Reproductive health failures following exposure to aldrin and dieldrin have been reported in numerous wildlife species such as fish, birds, alligators, harbor seals, and minks (Jorgenson, 2001). In vivo exposure in laboratory male murine models produced significant reductions in testosterone and LH (luteinizing hormone) serum levels, as well as a reduction in sperm count and degeneration of germ cells. The effects of aldrin and dieldrin in men reproductive function have not been extensively studied.

Lindane, also known as gamma-hexachlorocyclohexane (gamma-HCH), is another organochlorine that was used as both an insecticide and pharmaceutical treatment in the 1940s, resulting in wildlife and human exposure through inhalation, ingestion, and dermal absorption. In 2001, lindane was officially listed as a persistent organic pollutant by the Stockholm Convention. Since then, its use has been largely banned or restricted worldwide, with the exception of second-line treatment of lice and scabies. However, due to its extreme persistence in the environment and bioaccumulation properties, lindane is detected in air, surface water, groundwater, sediment, soil, ice, snowpack, fish, wildlife, and humans.

Lindane acts as both an AR antagonist (Fang et al., 2003) and an inhibitor of steroidogenic enzymes, such as StAR, HSDB3, and HSD17. Male gonads have been found to be particularly sensitive to lindane, with several studies in adult murine models showing degenerative changes such as tubular atrophy, spermatogenic cells necrosis, enlargement of the interstitial space, or decreased sperm production and quality. Following in utero or lactational exposure, lindane produces testicular alterations, a reduction in spermatogenesis, serum testosterone levels, testicular weight, spermatid and sperm counts, and increased chromatin abnormalities in epididymal sperm in male pups (Pagès et al., 2002). In humans, a sparse literature reveals possible associations between exposure to lindane and increased risk of cryptorchidism, sex hormone disruption, and a decline in sperm quality.

Herbicides

Linuron (3-(3,4-dichlorophenyl)-1-methoxy-1-methylurea) is a phenylurea herbicide used to control the growth of grass and weeds in crops such as soybeans. Linuron inhibits electron transport in chloroplast photosystem II complex, thereby preventing plant growth and promoting cell membrane destruction. Human exposure to linuron may occur through diet (food and water), when handling and applying the product, or by entering treated sites.

Linuron competitively inhibits the binding of androgens to AR and acts as a weak AR antagonist in transcriptional activation assays in vitro. In utero exposure to linuron drastically affects sexual differentiation and development by causing reduced anogenital distance and retained nipples as well as a high degree of epididymal malformation and testicular atrophy in male offspring. When administered to the dam during the critical period of sex differentiation, high doses of in utero linuron treatment also reduce ex vivo fetal testosterone synthesis in male offspring. In castrate-immature testosterone propionate-treated adult male rats, a 7-days treatment with linuron reduced testosterone and DHT-dependent tissue weights. Contrary to other pesticides such as vinclozolin or procymidone, malformed external genitalia or undescended testes are rarely displayed by linuron-exposed males (Gray et al., 2006). There are no studies available on associations between exposure to linuron and TDS-related phenotypes in boys or men.

Industrial Chemicals

Brominated Flame Retardants

Polybrominated diphenyl ethers (PBDEs) are organobromine compounds used as flame retardants. The family of PBDEs consists of 209 congeners classified by the average number of bromine atoms in the molecule. The available commercial PBDE products are not single congeners but rather mixtures of congeners. Due to their widespread use as nonchemically bound additives to a wide array of consumer products (e.g., building materials, electronics, furnishing, and textiles), PBDEs have become ubiquitous environmental pollutants. Since 2009, PBDEs are listed as persistent organic pollutants by the Stockholm Convention. Despite bans and voluntary withdrawals, lipophilic PBDE congeners persist in the environment, biomagnify up the food chain, and bioaccumulate in breast milk, serum, and adipose tissue.

The AR antagonistic activities of several PBDE congeners, metabolites and mixtures have been shown in vitro, in particular those of commercial mixture DE-71 and congeners BDE-17, -19, -28, -47, and -100. However, there is only limited evidence for the anti-androgenic properties of PBDEs to result in reproductive disorders. Peripubertal exposure to PBDEs in murine models results in delayed puberty and suppression of androgen-dependent tissue growth (Linares et al., 2015). In a single study, maternal exposure to PBDEs resulted in decreased sperm production in the offspring at adult age; such effects are corroborated by epidemiological studies in small cohorts on men recruited in fertility clinics showing associations between exposure to PBDEs and reproductive hormone levels or sperm motility. However, a study on partners of pregnant women showed conflicting results with the latter, reinforcing the need for large cohort studies that are more representative of the general population with background exposure. This past decade, PBDEs have been gradually replaced by novel mixtures of organophosphate flame retardants, but recent investigations suggest that these alternatives also constitute a toxic hazard.

Summary and Perspectives

If the field of environmental antiandrogens was born with agrochemicals, it has since expanded to a wide range of compounds, from industrial additives in everyday products to pharmaceutical drugs sold over the counter. Mechanistically, these chemicals can disrupt the physiological androgen pathway by antagonizing or modulating the androgen receptor, altering androgen production, or both. As more and more molecular based studies on antiandrogens are conducted, it has been suggested that this definition should be broadened to chemicals exerting antigonadotropic effects at large (for example, drugs altering the expression of hormones involved in gonadal differentiation, like the anti-Müllerian hormone, or in testicular descent, like insulin-like factor 3).

The evidence for implications of exposure to environmental antiandrogens on male reproductive defects from in vitro and in vivo laboratory models is ever-growing. However, the clinical and epidemiological evidence for effects in humans is still controversial: if some studies have found direct associations between exposure to some of these compounds and the incidence of cryptorchidism, hypospadias, pubertal delay, gynecomastia, or decreased semen quality, others have not. Such discrepancy is attributable to the complexity and variety of clinical protocols used, the degree of exposure, the subpopulation studied, the variables measured, the sample size, or, with regard to semen quality, the contribution of seasonal and geographical variations.

The growing body of evidence in support of the deleterious effects of environmental antiandrogens has prompted legislation to protect consumers, stimulating the chemical industry to develop alternative compounds. However, from DDT to phthalates and bisphenols, there is an inexorable history of regrettable substitutions entering the market, with some chemicals phased out at great cost in scientific, advocacy and legal efforts being replaced by hazardous substitutes. The scientific community is now calling for the use of proactive approaches to replace harmful chemicals, including a thorough investigation comparing the endocrine-disruptive effects of the candidate compounds to those of the original chemical.

Glossary

Androgens A type of steroidal hormones produced in the testis and adrenal glands of the males and primarily in the ovary and adrenal glands of the females. They have roles in the development of male secondary sex characteristics and the brain, reproduction, and regulation of lipid metabolism.

Antiestrogens A type of estrogen blockers or estrogen antagonists that inhibit or block the estrogen receptor activity or interfere with the production of estrogens in cells.

Aromatases A group of enzymes that convert androgens to estrogens.

Endocrine disruptors A group of artificially produced chemicals that show hormone-like properties and can interfere with the synthesis, metabolism, secretion, and transport, and the function of endogenous hormones of the endocrine system in the body.

Estrogens A type of steroidal hormones produced primarily by the ovary, adipose tissue, and the testis that has a role in the development of female secondary sex characteristics and the brain, reproduction, regulation of body fat, and the growth of long bones.

Introduction

Endocrine hormones and their signaling pathways play a vital role in the ability of organisms to develop from a fetus into a healthy adult. Steroid hormones such as estrogen and testosterone are known to play a critical role in sexual differentiation and reproduction. Estrone, a precursor to estrogen, and androsterone, a metabolite of testosterone, were isolated in the 1920s and 1930s. Then, it took another few decades before it was shown that radiolabeled estradiol was explicitly retained in estrogen-sensitive tissues compared to nonestrogen target tissues and that estrogen-sensitive tissues indeed contained extractable proteins known as estrogen receptors (Tata, 2005). Furthermore, only in the 1980s with the cloning of cDNAs were there enough protein materials to decipher the molecular mechanism of estrogen receptor action.

Today, we have a better understanding of how estrogen interacts with estrogen receptors and which tissues are sensitive to estrogens. Estrogen can transduce cellular signaling by two pathways, the classical, genomic pathway and nongenomic pathway (Fig. 1). In the genomic pathway (Fig. 1A), estrogen binds the ligand-binding domain of the estrogen receptor in the cytoplasm. With estrogen binding, the receptor is activated to move into the nucleus, where the receptors bind specific estrogen response elements (EREs) on target DNA as a dimer of receptors and regulate the expression of the target genes. Using this genomic pathway are two primary estrogen receptors, estrogen receptor alpha (ESR1), and estrogen receptor beta (ESR2), each responsible for modulation of its physiological functions in estrogen-sensitive cells (Kiyama and Wada-Kiyama, 2015). In the nongenomic pathway, estrogen can either activate a membrane-associated G protein-coupled estrogen receptor 1 (GPER1) or the classical ESR1 or ESR2 that then translocates to the membrane (Fig. 1B) (Arnal et al., 2017). Either of these nongenomic activation processes initiates a cascade of cellular signaling and cross talks of proteins, eventually leading to the recruitment of transcription factors and gene regulation in the nucleus.

In recent decades, research has been shifted to focus on how industrial and pharmacological chemicals and phytoestrogens in the environment may alter the availability of endogenous hormones and disrupt the action of estrogen-activated receptors, either in a genomic pathway or a nongenomic signaling cascade pathway (Fig. 1). The terms, environmental endocrine disruptors (EEDs) or endocrine disrupting chemicals (EDCs) have been coined to label any environmental chemicals that can mimic receptor ligand and disrupt normal endocrine function, causing abnormal cellular changes in the hormone-sensitive tissues and leading to the onset of diseases.

Classes of Ligand Mimics

Many endocrine disruptors (EEDs or EDCs) acting as receptor ligand mimics are industrial, synthetic chemicals or drugs with a similar structure to the natural hormone receptor ligands produced in the body (Fig. 2A and B). Binding of ligand mimics (Fig. 2C–G) to the receptor usually blocks the binding of the endogenous hormone ligand (Fig. 2A and B), and as a consequence, ligand mimics usually alter hormone-sensitive physiological reactions in the cell negatively. Although some ligand mimics show a clear preference for a specific receptor (distinguish between ESR1 and ESR2 receptors), most ligand mimics are promiscuous and inhibit the function of a variety of receptors including receptors for estrogens, androgens, progestins, and sometimes, adrenal

Fig. 1 Steroid hormone receptors regulate target genes by two distinct pathways. (A) In the classical, genomic pathway, estrogen (E) binds estrogen receptor (ER) and activates the receptor for the nuclear entry and dimerization. The dimer of receptors then binds estrogen response element (ERE) on the target gene to regulate its gene expression in the presence of co-activator (CA). (B) In a nongenomic pathway, E interacts with ER, which is modified to interact with a membrane receptor protein (such as epidermal growth factor or EGFR), which in turn activates the membrane receptor signaling cascade leading to the phosphorylation of transcription factors and the regulation of gene expression.

hormones in different tissues. Similarly, a ligand mimic can have opposite effects on cells, either estrogenic or antiestrogenic. For estrogen receptors, the ligand mimics can be classified as being estrogenic, stimulating the estrogen receptor activity in the presence of co-activator (Fig. 3A), or antiestrogenic, inhibiting estrogenic receptor activity in the presence of co-repressor (Fig. 3B). The ligand mimics in the first case are working as agonists, and in the second case, they are working as antagonists. In both cases, the ligand mimics interfere with the normal signaling mechanisms, either prolonging estrogen stimulus at inappropriate times or merely reducing or blocking any estrogen stimulus in the cell.

Whether the ligand mimics act as an agonist, or an antagonist is dependent on a complex set of variable contexts, among which are: what hormone receptors are expressed in the cell or tissue; what genes ligand mimics are acting on; what concentration of ligand mimics is used; and what other proteins, such as co-activators, co-repressors, kinases, or phosphatases, are permitted to interact with the hormone-receptor complex. One such example is a breast cancer drug tamoxifen that acts antiestrogenic in estrogen receptor-positive breast cancer cells but acts estrogenic in the endometrium by promoting Src kinase phosphorylation of the estrogen receptor. Phosphorylation stabilizes the interaction of estrogen receptor with co-activator and ERE on the target genes (Shah and Rowan, 2005). Prolonged exposure of tamoxifen in the endometrium can lead to endometrial cancer, which remains a primary concern for tamoxifen therapy on breast cancers (Shah and Rowan, 2005). Usually, antihormone ligand mimics are structurally different enough that they simply cannot bind the ligand-binding domain in the same way as the endogenous hormones, which blocks co-repressor release, thus restricting a room for co-activator binding to stimulate estrogenic activity (Fig. 3B).

Fig. 2 Chemical structures of natural ligands and endocrine disrupting ligand mimics. The ligands made in the body: (A) testosterone and (B) estrogen. Examples of antiestrogen endocrine disruptors: (C) bisphenol A (BPA), (D) methoxychlor, (E) 2,3,7,8-tetrachlorodibenzodioxin (TCDD), (F) polychlorinated biphenyl (PCB), and (G) benzo[a]pyrene, a type of polycyclic aryl hydrocarbon. The Structures of aromatase inhibitors: (H) imidazole and (I) glyphosate.

Fig. 3 Ligand mimics can be estrogenic or antiestrogenic. When a ligand mimic binds to a steroid hormone receptor, it may activate or repress the function of the receptor. (A) When the ligand mimics are estrogenic (agonist), the complex of ligand mimic (LM) and the receptor (ER) interacts with co-activators (CA) and induces the transcription of ERE-containing target genes. (B) When LMs are antiestrogenic (antagonist), the LM and ER complex interacts with co-repressors (CR) that keeps the LM and ER complex turned off and decreased the transcription of ERE-containing target genes.

Antiestrogens

There are several classes of ligand mimics that have been identified as antiestrogens or estrogen antagonists. They are classified by their mode of action: compounds that selectively bind the estrogen receptors and modulate their activity; compounds that act by binding and activating another nuclear receptor, which in turn inhibits estrogen receptor function; or compounds that reduce estrogen levels by inhibiting the cytochrome P450 enzyme aromatase (CYP19A1) needed in the production of estrogen. It should be noted that we have taken a relaxed definition of antiestrogens by including aromatase inhibitors, which may not act directly through estrogen receptors, but nonetheless, promote antiestrogenic activities.

Selective Estrogen Receptor Modulators (SERMs)

Many of the endocrine disruptors with antiestrogenic activities behave as selective estrogen receptor modulators (SERMs). SERMs are typically nonsteroidal in structure and act as competitive inhibitors for the binding of estrogen to the estrogen receptors (Kiyama and Wada-Kiyama, 2015). SERMs usually target specific estrogen receptors in estrogen-sensitive tissues, causing either estrogenic (agonist) or antiestrogenic (antagonist) activities. Examples of such SERMs are drugs such as tamoxifen, clomifene, and raloxifene, which are used to decrease estrogenic activities in estrogen-sensitive cancer cells. Similar chemicals, termed SERMs-like, are environmental endocrine disruptors such as an organochlorine pesticide methoxychlor (Fig. 2C), a component of plastics, bisphenol A (BPA) (Fig. 2D), and a methoxychlor derivative, 2,2-bis-(*p*-hydroxyphenyl)-1,1,1-trichloroethane (HPTE) (Fig. 4D). As with many of the metabolic derivatives of ligand mimics (Fig. 4), HPTE is at least 100 times more potent in biological activity (e.g., antiestrogenic or antiandrogenic activities) compared to the parental methoxychlor.

BPA is a small, synthetic, phenolic chemical (Fig. 2D) used in the manufacture of consumer products, such as the resin linings for canned foods and polyvinylchloride (PVC) plastics in medical tubings, toys and bottles, and water pipes. There are numerous variants of BPA including bisphenol C (BPC), a fluorinated derivative bisphenol AF (BPAF), used as a polycarbonate copolymer in high-temperature composites, electronic materials, and gas-permeable membranes, and a chlorinated tetrachlorobisphenol A (TCBPA), used as a fire retardant (Delfosse et al., 2014).

For many years, BPA was described as weakly estrogenic, having the ability to directly bind both ESR1 and ESR2, or as antagonists to both androgen and thyroid hormones (Welshons et al., 2006). However, more recent evidence indicates that BPA are SERMs, having the ability to serve as both estrogenic and antiestrogenic compounds, dependent on what tissues are examined, which receptors are present in the cell, what concentrations of BPA are used, and which BPA is examined (Welshons et al., 2006). BPA acts biphasically for ESR1 and ESR2 as a cell type-specific agonist at ≥ 10 nM or as an antagonist at ≤ 10 nM (Li et al., 2012). Both BPC and TCBPA inhibited ESR2 signaling, while only TCBPA, and not BPC, activated ESR1 signaling (Delfosse et al., 2014). Additionally, BPA can mediate its action through a nongenomic mechanism, where it activates a membrane-associated G protein-coupled estrogen receptor 1 (GPER1), which in turn associates with and activates the Egfr/Mapk3/1 pathway, influencing a cascade of cellular events (Fitzgerald et al., 2015) (Fig. 1B).

Methoxychlor is an organochlorine pesticide that replaced banned DDT and was used to control insects on many crops around the world (Fig. 2C). Although the production of methoxychlor was halted in the United States in 2003, methoxychlor is present in food and water samples and persists in the environment due to the evaporation/rain cycle redistributing waters on earth. Methoxychlor and HPTE are regarded as SERMs (Delfosse et al., 2014). In the mouse uterus, where ESR1 is the primary estrogen receptor expressed, methoxychlor operates as an ESR1 agonist and induces tissue growth (Tiemann, 2008). In contrast, methoxychlor operates as an antiestrogen in the ovary, where ESR2 is the dominant subtype and inhibits FSH/cAMP-induced estradiol synthesis mediated by ESR2 (Harvey et al., 2015). The results of methoxychlor exposure are the inhibition of follicle growth and increased atresia of antral follicles in the ovary.

Antiestrogen Activity Through Induction of Aryl Hydrocarbon Receptor

Not all antiestrogens inhibit estrogen signaling by directly binding to the classical estrogen receptors or the nongenomic membrane estrogen receptor. Several known ligand mimics work through binding and activation of other nuclear receptors. Well-studied, such compounds are polychlorinated biphenyls (PCBs), chlorinated dibenzo-*p*-dioxins (CDDs), and polycyclic aromatic hydrocarbons (PAHs) (Fig. 2E–G). Typically, CDDs are formed as industrial byproducts during the chlorination processes or incineration of garbage and fuel combustion. 2,3,7,8-TCDD (Fig. 2F) is produced during the chlorine bleaching process used by pulp and paper mills and during the manufacture of 2,4,5-trichlorophenol (2,4,5-TCP). 2,4,5-TCP is a chemical used in the manufacturing of bactericide hexachlorophene and the herbicide, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) (Manzetti et al., 2014). TCDD is persistent in the environment and bioaccumulates in the fatty tissue of the body. It is well known for being a compound found in Agent Orange, which contained herbicide 2,4,5-T to remove foliage during the Vietnam War (Manzetti et al., 2014). PAHs are also industrial byproducts of incomplete incineration and combustion, primarily from car emissions, burning coals, and in the manufacture of petroleum-derived substances.

On the other hand, PCBs are commonly used as coolants and lubricants in transformers, as flame retardants, and used in microelectronic circuits, capacitors, and other electrical equipment, since they do not burn easily and make good insulator material (Manzetti et al., 2014). It should be noted that the PCB being referred to here is 3,3',4,4',5-pentachlorobiphenyl (PCB126), which is known to act similarly to TCDD (Matthews et al., 2007). There is a variety of PCBs, and other PCBs may act differently, with most of

Fig. 4 Chemicals are metabolized to their more active metabolites in the body. (A) Chlorinated aromatic hydrocarbon insecticide DDT is metabolized to DDE and DDD. (B) Plasticizer diester phthalates are metabolized to monoester phthalates. (C) Dicarboximide fungicide vinclozolin is metabolized to M1 and M2. (D) Organochlorine pesticide methoxychlor, which was a replacement for DDT, is metabolized into its active metabolite HPTE.

them being estrogenic. TCDD, PAHs, and PCBs are suspected carcinogens and are implicated in cancer, reproductive disorders, and neurological and developmental disorders.

Upon entering the body, the dioxin and related compounds are taken up into tissues, where they activate the aryl hydrocarbon receptor (AHR) (Fig. 5). Upon activation, AHR receptor interacts with aromatic hydrocarbon receptor nuclear translocator (ARNT, or HIF1 β) in the nucleus, which together associates with dioxin-response elements (XRE) on DNA and regulates AHR-regulated genes. The antiestrogen action of the compounds like TCDD and PCB126 comes from their activation of the AHR signaling pathway, which in turn recruits ESR1 as a co-activator (Fig. 5) to AHR/ARNT bound dioxin-response elements (Matthews et al., 2007). This recruitment of ESR1 removes the estrogen receptors from the normal transcription activity on estrogen-responsive genes, leading to antiestrogenic activity.

Antiestrogen Activity Through Inhibition of Aromatase

The third class of antiestrogenic chemicals does not interact with the estrogen receptors directly or indirectly but modulates the production of estrogen and the homeostasis of estrogenic activities in the cell. The principal target for this type of endocrine disruptors is the cytochrome P450 enzyme aromatase (CYP19A1), the enzyme responsible for converting testosterone to estradiol, and androstenedione to estrone (Blakemore and Naftolin, 2016) (Fig. 6). CYP19 is expressed in many tissues including the ovary,

Fig. 5 Dioxins and dioxin-like chemicals act as antiestrogens through the activation of the aryl hydrocarbon receptor pathway. Dioxin and dioxin-like compounds bind and activate the aryl hydrocarbon receptor (AHR), which then moves into the nucleus and dimerizes with ARNT. Upon binding of the aryl hydrocarbon receptor response element (XRE), the estrogen receptor (ER) is recruited to the AHR/ARNT complex as a co-activator. The recruitment of ER to the AHR/ARNT complex removes ER from being able to bind and regulate ERE containing target genes, thus decreasing estrogenic activity.

Fig. 6 Aromatase converts androgens into estrogens through the removal of the 19-methyl group of androgen in three successive oxidation steps.

testis, brain, adrenal, placenta, adipose, bone, and skin, but regulation of CYP19 expression is highly tissue-specific with alternative promoter usage and cross-talks with other second messengers, such as cAMP. Changes in aromatase expression (loss or gain of expression) have been associated with numerous male and female reproductive and immunological disorders, as well as in the induction of cancer.

The aromatase inhibitors used in agriculture are nonsteroidal chemicals called azoles (epoxiconazoles, imidazoles, and triazoles) that have antifungal activity, and glyphosate and glyphosate-containing compounds, like Roundup, that are herbicides (Richard et al., 2005) (Fig. 2H and I). Many aromatase inhibitors were developed for the treatment of breast cancer, endometriosis, and prevention of menopausal symptoms as well (Blakemore and Naftolin, 2016). Successfully used clinical aromatase inhibitors are letrozole and anastrozole that inhibit the aromatase activity by binding the heme group of aromatase reversibly (Blakemore and Naftolin, 2016). Additionally, estrogen receptor and aryl hydrocarbon receptor could be involved in the expression of aromatase. The gene for aromatase has both EREs and XREs in the promoter (Sanderson, 2006). It means that the expression of aromatase can be downregulated by antiestrogens through classical estrogen receptors or by dioxin-like chemicals through aryl hydrogen receptors. Another chemical that reduces aromatase activity by aryl hydrogen receptor and estrogen receptor is benzopyrene, a dioxin-like PAH from incomplete combustion of organic materials (Alharthy et al., 2017).

Reproductive Disorders and Cancer

As many environmental disruptor chemicals are components of industrial/consumer products in large quantities, they have a great potential to contaminate the environment. Humans are in direct contact with these chemicals, setting up the possibility of disease onset. Routes of entry into the body occur in any number of different ways, from ingestion through food and water, inhalation of the dust particles in the air, to absorption through the skin. Antiestrogen endocrine disruptor chemicals have been linked to many different diseases, be it the initiation and promotion of different types of cancer, or the induction of various types of reproductive disorders. As estrogen plays a role in maintaining the hormone balance in both sexes, it is not surprising that

these compounds can induce diseases in both males and females. In this section, we will focus on the diseases more commonly observed in males over those found in females and focus on chemicals known to have antiestrogenic activities (BPA, methoxychlor, and dioxins).

As endocrine disruptors with antiestrogenic activities are targeting estrogen signaling, it is no surprise that BPA, dioxin, and methoxychlor affect the reproductive system, where estrogen signaling function is essential. The reproductive disorder in males induced by endocrine disruptors with antiestrogenic activity range from mild (a small decrease in sperm count) to major as in hypogonadism, infertility and testicular cancer. In humans, fetal BPA exposure has been linked with feminization, shorter anogenital distances, increased incidences of hypospadias, and undescended testes (Fernandez et al., 2016; Komarowska et al., 2015; Miao et al., 2011). In rodents exposed perinatally to BPA, observations have been made for defective spermatogenesis, increase in meiotic cell arrest, increased apoptosis, decreased sperm quality, and more recently, transgenerational impairment of male fertility (Williams et al., 2014).

Additionally, BPA exposure has been associated with high risks of developing prostate cancer, testicular interstitial cell tumors, and mammary cancer in males (Sweeney et al., 2015; Seachrist et al., 2016; Wang et al., 2017). Supporting this, young men with histopathologically verified prostate cancer had higher serum levels of BPA than healthy controls.

For methoxychlor, different dosing and concentration schemes have identified multiple disruptions in male reproductive function. Perinatal exposure to mice showed a reduction in serum testosterone levels, an increase in estradiol concentrations, a decrease in pachytene and spermatid cell numbers, and increases in Leydig cell numbers (Du et al., 2014). Some of these changes were attributed to decreased androgen levels and altered estrogen metabolism enzymes, notably a decrease in CYP11 and an increase CYP19 expressions. Similar to BPA, the embryonic exposure of pregnant rats decreased sperm number and motility and increased germ cell apoptosis (Anway et al., 2005). These changes were transmitted to male progeny in multiple generations (first to fourth generations) by epigenetic mechanisms (Anway et al., 2005). Further investigation is required to elucidate the exact mechanism by which methoxychlor interferes with epigenetics.

TCDD, PAHs, and PCBs are suspected carcinogens and are implicated in cancer, reproductive disorders, and neurological and developmental disorders. These chemicals working through the AHR pathway have been observed in rodent males to cause decreases in androgen levels and sperm counts, reductions in gonadal, seminal vesicle, and prostate weights, hypospadias, and delays in male puberty. The exact magnitude of these decreases was found to vary, depending on the concentration and timing of exposure. A low dose of TCDD has been found to decrease sperm quality, reduce androgen levels and cause transgenerational changes in fertility over multiple generations (Sanabria et al., 2016). Moreover, dioxin-like compounds such as PCBs have been positively correlated with increased incidence of prostate cancer and male breast cancer (Prins, 2008; Sweeney et al., 2015).

A transparent common theme emerging from these studies is that the type of diseases initiated by ligand mimics or the severity of disease is dependent on the concentration and the time of exposure (embryonic versus postnatal) of the ligand mimics. Exposure to ligand mimics during embryonic and perinatal times, which span the critical periods of sexual differentiation, masculinization, and development, seems to have more dramatic effects on reproductive disorders or cancers than postnatal times. Accordingly, many of the adult diseases are thought to originate from fetal and perinatal exposures to endocrine disruptors. At the same time, the concentration of ligand mimics has a high influence on whether a ligand mimic operates as an estrogen or an antiestrogen mimic. At a low dose, the ligand mimics may be estrogenic, whereas, at a high dosage, the ligand mimics may be antiestrogenic, or vice versa. Low concentration of ligand mimics could have totally opposite physiological effects from the high concentration.

However, not much information is available in the literature, directly linking the mechanisms of action to pathological effects on male reproduction and cancers for each ligand mimic following in vivo exposures in animals or real-life exposures to humans. As endocrine disruptors with antiestrogenic properties discussed here are ubiquitously contaminating the environment and humans are continually exposed and at risk to develop pathological conditions, there is urgent need to fully decipher the mechanisms of each ligand mimic underlying specific male reproductive disorder or cancer. Understanding the mechanisms of estrogenic and antiestrogenic ligand mimics may provide guidance for the development of potential counteractive therapy for different reproductive disorders and cancer.

TR	Thyroid hormone receptor
YES	Yeast estrogen screen

Background

There are many chemicals present in the environment that have been reported to disrupt normal endocrine function (TEDX, 2017). A number of these chemicals, used as insecticides, herbicides and fungicides, components of plastic and resins, and in a wide variety of other products, bind to estrogen receptors and stimulate or inhibit estrogenic responses (they act as receptor agonists or antagonists). Other chemicals, such as atrazine, glyphosate, lindane and bisphenol A (BPA) impact estrogen responses by altering the activity of the estrogen synthesizing enzyme, aromatase, in addition to impacting receptor function (Table 1).

Estrogens as a hormonal class were initially recognized in animal science and agriculture with respect to their effects in female reproduction and their responses generated in the female reproductive tract. However, after the estrogen receptor proteins and the mechanisms of estrogen responses were recognized beginning in the 1960s, estrogens have been defined specifically, as for all other hormones in endocrinology, by interactions with the estrogen receptor signaling systems. Specifically, this occurs by actions which start with specific, high affinity, saturable binding to and activation of estrogen receptors, and not by the final response(s), which are usually regulated by many additional factors and mechanisms in the animal's physiology (Fig. 1).

Therefore, unlike classical toxicology, where a chemical is characterized by its measurable effects on generic responses through unknown mechanisms, hormones and chemicals with hormonal activity, such as estrogens and xenoestrogens, are by definition known first by the mechanism of action through the linked hormone receptor signaling systems. This links the chemical immediately to the existing literature spanning over a century on the sensitive, specific estrogenic effects and responses, including normal reproduction, normal nonreproductive physiology, and estrogen-stimulated cancers. This crucial difference in the starting points and consequent approaches has been responsible for the failure of classical toxicology to adequately identify and characterize estrogenic endocrine disrupting chemicals before incontrovertible and massive human damage has already occurred, as for the DES tragedy.

Table 1 Common xenoestrogens (A) and disruptors of estrogen signaling (B)

A. Xenoestrogens
Insecticides
o,p'DDT
Flame retardants
PBDE's
PCB's
Herbicides
Glyphosate
Plasticizers
Phthalates
Plastic or resin monomers
Bisphenol A (BPA)
Bisphenol S (BPS)
Bisphenol F (BPF)
Detergent Alkylphenols
Octylphenol
Nonylphenol
Pharmaceuticals
Diethylstilbestrol (DES)
Ethinylestradiol (EE)
Phytoestrogens
Genistein
Daidzein
Biochanin A
Coumestans
Resveratrol
Mycotoxins
Zearalenone
Zearalenol
Metals
Cadmium
Nanoparticles
Gold Nanoparticles (GNP)
B. Aromatase modulators, estrogen antagonists, antagonists related to estrogen signaling, and other mechanisms
Aromatase Modulators
Glyphosate
Atrazine
BPA
Lindane
Estrogen Antagonists
Lindane
Antagonists for Estrogen-Related Receptor α (ESRRA)
Toxaphene
Chlordane
Other Mechanisms
Insecticide
Toxaphene
Fungicide
Hexachlorobenzene
Endosulfan
Nicotine
Pyrethroids

Diethylstilbestrol (DES): An Latrogenic Tragedy Predicted Long-Latency Effects of Xenoestrogens

Compared to other components of the endocrine system, there is a considerable amount known regarding the mechanisms of estrogen action. One reason is that there has been interest in developing estrogenic drugs to impact female fertility since the early 1900s (Dodds and Lawson, 1936). The publication of the estrogenic activity of the potent estrogenic drug diethylstilbestrol (DES) in 1938 (Dodds et al., 1938) resulted in millions of women being administered DES during pregnancy between the late 1940s through 1972 in the misguided belief that supplemental estrogen would reduce the incidence of miscarriage. Instead, fetal exposure to DES

Fig. 1 The effect of very low (femtomolar) to high (nanomolar) concentrations of estradiol on cell proliferative response (percent of maximum response) in relation to percent receptor occupancy of MCF-7 human breast cancer cells. The data show that the physiological range for proliferative response to estradiol is within the sub picomolar to very low picomolar range. Above the nanomolar range, nuclear estrogen receptors are saturated, and no additional estradiol can cause an increase in receptor occupancy and thus receptor-mediated response (as proliferation here). In this cell culture system, the peak proliferative response occurs at the K_d for estradiol (50% receptor occupancy), while 50% of the maximum response (the EC_{50}) occurs at 100-fold lower estradiol concentration and approximately 1% receptor occupancy. Thus, estradiol (and other hormones) acts via receptors at very low percent receptor occupancy, where the increase in estradiol concentration is approximately proportional to an increase in receptor occupancy that mediates an increase in the proliferative response. Derived from data published in Welshons, W. V., Thayer, K. A., Judy, B. M. et al. (2003). Large effects from small exposures. I. Mechanisms for endocrine-disrupting chemicals with estrogenic activity. *Environmental Health Perspectives* **111**, 994–1006.

during the first and second trimesters disrupted development of the reproductive system in both males and females (Reed and Fenton, 2013), and also impacted neurobehavioral development (Hines, 2011). Unfortunately, since fetal DES exposure did not result in an easily identified external malformation, the use of DES continued for decades before it was identified as a human carcinogen. Fetal DES exposure was related to clear cell adenocarcinoma of the vagina and cervix in female offspring in their teens and 20s, and an increase in the risk of breast cancer in their 40s (Palmer et al., 2006). The DES iatrogenic tragedy alerted the medical community to the hazards of exposure to drugs that could cross the placenta, but sadly, the implications of this tragedy for exposure to environmental chemicals with estrogenic activity has remained largely unnoticed by clinicians (Cohen and vom Saal, 2017).

In response to the DES tragedy, the US National Institute of Environmental Health Sciences (NIEHS) began a research program aimed at elucidating life-history effects of DES exposure during development using mice as the model organism. In a number of cases, effects were observed in DES-exposed mice that led clinicians to look for the same effects in DES exposed human offspring, and only then did clinicians observe in humans the effects that had been observed in mice (Haney et al., 1986). Of great concern is the finding in mice that fetal DES exposure not only harmed the offspring (F1 generation) of the exposed mothers, but the offspring (F2) of the F1 exposed females; that is, the grandchildren of the DES exposed mother (Newbold et al., 2006), tentatively confirmed in a human epidemiological study (Kalfa et al., 2011). The multigenerational impact of environmental chemicals, including those with estrogenic activity, as well as effects on subsequent generations (transgenerational—beyond F2) is now a major research focus, based on findings that hormones and hormonally active chemicals can alter the epigenetic mechanisms that control gene function, particularly during critical periods in tissue differentiation. These findings are predicted to be due to epigenetic changes in the germ line that somehow escape the deprogramming and/or reprogramming of the genome that would otherwise occur without chemical exposure (Nilsson and Skinner, 2015).

The NIEHS research on DES effects identified that there was a very close relationship between effects observed in mice and effects found in human DES exposed male and female offspring (Newbold, 1995; Newbold et al., 2006). The experimental demonstration that the laboratory mouse accurately predicted virtually all developmental effects of an estrogenic drug in humans has had a profound impact on the study of environmental chemicals with estrogenic activity. In particular, the DES literature led to a focus on the long-term effects of exposure to environmental chemicals during “critical periods” in organogenesis, during which epigenetic changes impact the differentiation and life-long functioning of organ systems. There is now a medical/scientific society whose focus is on the “Developmental Origins of Adult Health and Disease” (the DOHaD Society and journal).

Estrogenic Endocrine Disrupting Chemicals

The potential impact of chemicals in the environment, both naturally occurring and manmade, that could disrupt the functioning of the endocrine system was first raised at a meeting held at Wingspread in Racine Wisconsin in 1991, and a review of endocrine disrupting chemicals (EDCs) was published in 1993 with a focus on the long-term consequences of exposure during development (Colborn et al., 1993). At that time there was already evidence that a number of EDCs had estrogenic activity, and in 1996 the US Congress passed the Food Quality Protection Act (FQPA) that mandated that the EPA screen pesticide chemicals for estrogenic activity. The EPA expanded their screening program, The Endocrine Disruptor Screening Program (EDSP), to include disruption of androgen and thyroid hormones as well as estrogens. A combination of industry interference, EPA mismanagement, and then a lack of funding, resulted in the failure of the EDSP (Zoeller et al., 2012). However, over the past 25 years thousands of studies have been published documenting the effects of EDCs using *in vitro* assays, experiments with laboratory animals, observational and experimental studies with wildlife, and human epidemiological studies. Environmental estrogens (xenoestrogens) have been the focus of a large number of these EDC studies.

Ligand-Receptor Interaction: Affinity vs. Potency

One of the crucial issues regarding xenoestrogens that has created considerable confusion is that, in general, xenoestrogens exhibit a lower binding affinity relative to estradiol for the classical nuclear estrogen receptors, estrogen receptor alpha (ER α) and estrogen receptor beta (ER β). This has led those who believe that dose–response relationships for EDCs, and all other environmental chemicals, are monotonic and exhibit a threshold below which there is no effect to not be concerned with the potential for these chemicals to pose a hazard to human health. However, it is now well documented that neither of these assumptions is valid for EDCs, which do not exhibit thresholds and show nonmonotonic dose–response relationships (Sheehan, 2006; Vandenberg et al., 2012); despite the extensive data, these remain the core assumptions (monotonic dose responses with thresholds) used by regulatory agencies in chemical risk assessments (vom Saal and Sheehan, 1998; Zoeller et al., 2012). In addition, it is well recognized that affinity (K_d) of a chemical for a receptor is not equivalent to its potency (EC₅₀) (Welshons and Jordan, 1987), which is impacted by coregulatory proteins (coactivators and corepressors) that together with the receptor form the transcriptional complex. For example, using HeLa cells transiently transfected with ER β , the increase in response to estradiol was significantly greater with the co-activator TIF2 relative to SRC-1, demonstrating that estimations of potency based only on affinity of a ligand for a receptor was not valid (Routledge et al., 2000).

The issue of potency is also greatly complicated by the fact that while in chemical risk assessments only one chemical is tested, the typical person is exposed to hundreds or thousands of chemicals that can potentially interact with each other. The Centers for Disease Control and Prevention (CDC) has managed to obtain funding from the US Congress to examine 308 chemicals out of a much larger number that there is a need to examine in the US population; one glaring example of the need to expand the number of chemicals being tested is that the CDC does not determine the levels of glyphosate in the US population, although glyphosate is the highest volume herbicide used in the US and worldwide, and there is evidence that glyphosate is a carcinogen and an EDC (Myers et al., 2016).

Concentration Additive Effects of Xenoestrogens

Kortenkamp and colleagues have published studies concerning the consequences of examining mixtures of estrogenic chemicals, with each xenoestrogen being added to the mixture at a concentration that individually produced no observable effect (the NOEC). They tested a mixture of eight xenoestrogens using the yeast estrogen screen (YES) and showed that the xenoestrogen mixture stimulated a response consistent with “concentration addition” (Silva et al., 2002). They also showed the same result when a mixture of 11 xenoestrogens (each at concentration that individually produced no effect) was tested in combination with a dose of estradiol that alone stimulated a significant response (Rajapakse et al., 2002). Thus, very low doses of estrogenic chemicals that act through the same receptor can have additive effects that can alter the response to the potent steroid estradiol, even though when tested individually, the xenoestrogen dose tested would have been declared “safe.” In addition, a take-home message from these studies is that testing chemicals individually with the objective of establishing a NOEC or no adverse effect level (NOAEL) results in an invalid estimation of a safe exposure level, because we are not exposed to only one chemical at a time.

Synergistic Effects of Xenoestrogens

Synergy is a naturally occurring feature of estrogens. Estradiol stimulates mammary gland progesterone receptors, and after a brief exposure to estradiol, there is a substantial synergistic effect of estradiol with progesterone responsiveness by stimulation of progesterone receptors. In addition, estradiol stimulates prostate androgen receptors (vom Saal et al., 1997; Taylor et al., 2012) and uterine oxytocin receptors (Richter et al., 2004). The interaction of estrogens with receptors for other hormones thus leads to synergistic as opposed to additive effects, which are observed when different estrogens produce similar effects through the same receptor mechanism.

Rapid Signaling via Nonnuclear Estrogen Receptors

A major change in understanding estrogen action occurred with the discovery that estrogens acted through receptors associated with rapid signaling systems. While for some time there had been evidence for rapid responses to estrogen that were not consistent with responses mediated by changes in gene activity mediated by nuclear transcription factors, there is now an extensive literature on the cellular response pathways that mediate the rapid responses to endogenous and xeno-estrogens. Of great importance, the potency of xenoestrogens, such as BPA, are equivalent to estradiol for effects mediated by these cell membrane associated receptors.

For example, in rat cerebellar cortex neurons in primary culture, estradiol activated rapid estrogen-mediated extracellular signal-regulated kinase (ERK1/2) signaling with a peak response occurring at 10^{-10} M and another peak occurring at 10^{-7} and 10^{-6} M, while at 10^{-9} and 10^{-8} M the response was at baseline. A nonmonotonic dose-response profile is common for membrane-receptor mediated responses to hormones, and the multiple peaks at 1000–10,000 fold different doses suggest that different mechanisms are involved in the peak at 10^{-10} M as opposed to 10^{-6} M. In addition, in this study the response to the same doses of BPA administered alone tracked identically with estradiol, in sharp contrast to the often-stated conclusion that BPA is a “weak” estrogen. However, when the low-dose peak response dose of estradiol (10^{-10} M) was coadministered with increasing doses of BPA, there was a linear inhibition of estradiol phosphorylation of ERK1/2 by BPA beginning at 10^{-12} M BPA (Zsarnovszky et al., 2005).

This finding of antagonism by BPA of estradiol-mediated activation of responses in the brain is consistent with in vivo findings in African green monkeys that BPA completely abolished the stimulatory effect of 10^{-10} estradiol on spine synapse formation in the cerebral cortex and hippocampus, and thus acted in these areas of the primate brain as an estrogen antagonist. The ability of BPA to interfere with spine synapse formation has clear implications for cognitive functioning (Leranth et al., 2008). With regard to BPA acting in some tissues as an agonist or antagonist, this is not unique and is why BPA is referred to as a selective estrogen receptor modulator or SERM (Jordan and Murphy, 1990). Virtually all xenoestrogens have been identified as SERMs as well.

Nonadditive Effects of Mixtures of Xenoestrogens via Membrane-Associated Estrogen Receptors and Nonmonotonic Dose-Response Relationships

Watson and colleagues identified modulation of ERK1/2 signaling in rat pituitary (GH3/B6/F10) cells in response to endogenous estrogens as well as numerous xenoestrogens, including phytoestrogens, alkylphenols, and BPA. ERK1/2 activation by estradiol and these xenoestrogens occurred in the femtomolar range, but the response profiles were unique for the different xenoestrogens relative to estradiol. Similar to findings by Zsarnovszky, the xenoestrogens showed nonmonotonic dose-response curves. However, when estradiol and each xenoestrogen were examined as a mixture, entirely different, typically monotonic, response profiles were observed. Thus, simple concentration additive effects were not observed, since each chemical had a unique response profile. This is expected for xenoestrogens that act as SERMs and multiple response mechanisms are involved. In addition, using selective agonists of ER α and ER β , the low-dose ERK1/2 activation was shown to be via ER α (Jeng et al., 2009; Jeng and Watson, 2011).

Experiments with mouse pancreatic beta cells identified unique effects of nonnuclear ER α and ER β , and also shed light on the intracellular pathways that can mediate nonmonotonic dose-responses. Specifically, glucose entry into pancreatic beta cells results in K_{ATP} channel closure, membrane depolarization, opening of voltage-gated Ca²⁺ channels and Ca²⁺ influx, which results in exocytosis of insulin granules (first phase insulin release). However, including either a 0.1 or 1 nM concentration of BPA resulted in a diminished Ca²⁺ influx, while 10 or 100 nM BPA had no effect relative to negative control levels. Use of selective agonists and antagonists for ER α and ER β and ER β knockout mouse cells revealed that the low-dose BPA effects on Ca²⁺ channels and insulin release were mediated via activation of ER β pathways. In contrast, the 100 nM BPA concentration inhibited the low-dose BPA effect via activation of ER α , which opposed ER β actions on Ca²⁺ currents by acting through P13K kinase, resulting in a nonmonotonic dose response. ERK1/2 pathways did not contribute to these findings. In pancreatic beta cells there is thus an activation of ER β at very low doses of BPA and at higher doses (≥ 10 nM), the low-dose BPA effect is blocked via pathways mediated by ER α (Villar-Pazos et al., 2017).

Importantly, nonmonotonic dose-responses are observed due to the interaction of xenoestrogens with nuclear ERs due to differences in the profile of gene expression as the dose increases. For example, high doses of estradiol result in gene expression for growth factors that inhibit the proliferation stimulated by estradiol at low doses in MCF-7 breast cancer cells (Cosér et al., 2003). One possibility for the marked difference in gene expression at subpicomolar and picomolar concentrations of estradiol, as opposed to nonphysiological nanomolar concentrations is that high doses of estradiol bind to receptors for other hormones, such as androgen receptors (AR), which is referred to as receptor cross-talk. The cross talk with receptors for androgen and thyroid hormone at increasing doses of BPA could be a mechanism that accounts for some nonmonotonic dose responses identified for BPA (Vandenberg et al., 2012). Binding of BPA to AR or TR antagonized the action of androgens and thyroid hormone (Fig. 2). This is a reason that if one is interested in the estrogenic actions of BPA, they cannot be determined by testing at doses that saturate estrogen receptors, because estrogen-receptor saturating doses lead to interactions with receptors for other hormones as well as oppose the saturated estrogenic actions.

Fig. 2 BPA acts as an estrogen receptor agonist (+) for membrane and nuclear estrogen receptors at femtomolar and nanomolar concentrations, respectively. The binding of BPA to androgen receptors (AR) and thyroid hormone receptors (TR) at much higher concentrations (at which both membrane and nuclear estrogen receptors are saturated) is antagonistic (–) to androgen and thyroid hormone action. As shown in studies of pancreatic beta cells (Villar-Pazos et al., 2017), the high-dose binding with different receptors (a common feature of hormones) can account for non-monotonic dose–response curves.

All Environmental Chemical Interactions With the Normal Receptor-Mediated Estrogenic Signaling Are Disruptive

Estrogens in the organism are active and required throughout life to induce normal fetal development and to regulate normal physiology in the adult (males as well as females). For these reasons, the interactions of external environmental estrogenic EDCs, which are not controlled by the animal, will be disruptive and adverse to the normal hormone action and all of the physiology controlled by estrogens, known now or discovered in the future. The reasons for this are as follows. (1) A xenoestrogen of identical action to the endogenous estrogens (that is, a full agonist), will add to the normal signaling to estrogenize the animal abnormally, including effects on estrogen-stimulated cancers. The additivity of xenoestrogens with each other was described above. (2) A xenoestrogen of identical action to endogenous estrogens, but which can stimulate only a partial response (that is, a partial agonist), will blunt the normal signaling in the animal, inhibiting the normal effects of endogenous estrogens. (3) A xenoestrogen which binds to estrogen receptors but activates responses different from the endogenous estrogens (that is, a SERM), will change normal signaling in the animal and disrupt normal estrogen actions. (4) A chemical which binds to estrogen receptors but does not activate the receptor (that is, an estrogen antagonist or pure antiestrogen), will by competitive inhibition prevent the binding of endogenous receptors, and inhibit normal signaling by the endogenous estrogens, disrupting all of the physiology normally controlled by endogenous estrogens. And (5), environmental chemicals that change endogenous estrogen synthesis (aromatase modulators), or normal estrogen-controlled receptor activation (ligand-independent activators of steroid receptors; see below), or any other aspect of estrogenic hormone action and control, will change normal estrogen-regulated physiology in one direction or another. As indicated previously, for all of the above cases the presence of a threshold has been shown to not exist for ligand–receptor interactions (Sheehan, 2006).

Disruption of Estrogen Homeostasis by Altering Estrogen Synthesis and Ligand-Independent Effects

Another mechanism by which environmental chemicals can act as endocrine disruptors is by altering the activity of the enzyme, aromatase, which is the estrogen synthesizing enzyme that is sometimes referred to “estrogen synthetase.” A number of chemicals alter aromatase activity: The herbicide atrazine increases aromatase activity in the ovary (Holloway et al., 2008). BPA increases aromatase activity in the prostate, and the increase in intracellular estradiol may contribute the effects of very low doses of BPA on the prostate through additive effects (Arase et al., 2011; Taylor et al., 2012). In addition, BPA and the insecticide lindane increase aromatase activity in the placenta (Nativelle-Serpentini et al., 2003, while glyphosate, as well as other chemicals in commercial formulations of this herbicide, decrease aromatase activity in placenta cells (Defarge et al., 2016).

There is evidence that steroid receptors can be activated without binding of a ligand to the receptor, which is referred to as a “ligand-independent” mechanism. This can result from stimulation of growth factors, such as EGF and IGF-1, that bind to their receptors, which then leads to activation of the growth factor receptor and subsequent phosphorylation and activation of the estrogen receptor. There are a number of examples of ligand-independent effects: for example, BPA and DES have been reported in experiments involving cell and organ culture to produce ligand-independent effects (Gupta, 2000; Mesnage et al., 2017).

Regrettable Substitutions

In the United States, the EPA has only banned the use of a few chemicals over more than 40 years. The FDA has an even more dismal record. The US congress passed the Food Additive Amendment in 1958, which was intended to protect the public from harmful chemicals by requiring an affirmation of safety by the FDA and toxicity testing before they were used in or on foods. Specifically, the FDA supposedly considers chemicals to be safe when there is “a reasonable certainty in the minds of competent scientists that the substance is not harmful under the intended conditions of use” [21 CFR §170.3(i)]. In other words, a chemical is considered unsafe until proven safe, but sadly, exactly the opposite is the case for the “food” division at the FDA, in sharp contrast to the approach used in the “drug” division of the FDA. The 1958 law included chemical ingredients intentionally added to foods or “direct additives” such as preservatives, flavors, sweeteners, and emulsifiers, as well as chemicals unintentionally added to food, such as chemicals used in production, packaging, preparation and transporting that through migration or leaching may enter the food supply; one of the major examples is BPA that is used in food packaging and the resin lining of food and beverage cans. The law required the FDA to consider chemicals that were structurally similar as being potentially similar to each other in terms of toxicity unless proven otherwise. The FDA has simply chosen to ignore this law (Maffini and Vogel, 2017). The consequence of the EPA ignoring the requirements of the Food Quality Protection Act, and of the FDA ignoring the Food Additive Amendment is that chemicals that are found to pose a hazard to animal and human health, such as BPA and its analogues, remain unregulated by federal agencies in the United States. This also leads to chemicals that pose a hazard to human health being used to replace (regrettably) other chemicals that pose a hazard to human health.

Similar to smoking, it has been cities and states, and other countries, that have regulated BPA, and there are ongoing efforts to regulate BPA analogues. Due to public pressure on corporations, there has been a gradual voluntary transition to the use of other chemicals as substitutes for BPA. Many of these are now being referred to as “regrettable substitutions,” because they are BPA analogues that are structurally similar to BPA and show estrogenic activity in a variety of assay systems with ER α and ER β (examples are: BPB, BPF, BPS, BPZ, BPAF, BPAP, TM-BPA, MH-BPF; there are dozens of other BPA analogues). In some cases, the replacement analogues are worse than BPA, but they are being used in “BPA-free” products, which the public thus assumes are safe (Stossi et al., 2014; Rochester and Bolden, 2015; Mesnage et al., 2017). There are other examples of “regrettable substitutions,” such as the use of brominated flame retardants (polybrominated diphenyl ethers or PBDEs) as replacement chemicals of polychlorinated biphenyls (PCBs), and over the last 40 years PBDEs have been shown to be as bad or worse than PCBs. Attempts to increase federal oversight of chemicals prior to their use in products, with the potential for widespread exposure, have not been successful in the United States, while the EU has taken a more precautionary approach.

Politics of Xenoestrogen Evaluation, and Failure by Regulatory Agencies to Protect the Public

A consequence of political effects on evaluation of endocrine disruptors that are in commerce is that reading just the abstract of a paper is dangerous in this field. This is because, while falsification (changing existing data) or fabrication (creation of data that did not exist) reported as experimental findings are defined as prosecutable scientific misconduct, conclusions drawn in a publication which are contraindicated by the data, that is statements characterizing results in the text of a paper which are blatantly opposite to the data, are not administratively/legally defined as scientific misconduct. There are a number of examples of this for studies involving BPA, one of the most glaring being a study published by FDA scientists in which they concluded in the abstract that “No age-related changes were seen in internal exposure metrics for aglycone BPA in monkeys,” which was contradicted by their findings (Doerge et al., 2010).

Therefore, unlike in most of the scientific literature and in the independent academic literature, for studies involving chemicals in commerce it is essential to the evaluation of experimental findings to read the paper's results and examine the data, to determine independently whether the data in fact support the conclusions as stated in the Abstract or the Discussion. Unfortunately, in many cases in regulatory and industry papers claiming some version of “no harm,” the data may clearly show the opposite of the written conclusions: an example was the inappropriate analysis of data to justify the conclusion of “no harm” in an industry-funded BPA study (Elswick et al., 2000) that was harshly criticized by NIH statisticians who had reviewed the study for the National Toxicology Program (Haseman et al., 2001).

In summary, the current approach by federal regulatory agencies of considering environmental chemicals safe until “proven” not to be safe (the opposite of the law in the United States) has led to thousands of chemicals, an unknown number of which may have estrogenic endocrine disrupting activity, being used in food and food packaging, as well as in a wide range of consumer products. This approach is leading to wide-spread exposure of the general population to chemicals about which, in many cases, nothing is known about the potential hazards posed to human and animal health. Even when there is extensive documentation of harm, the chemical industry and their lobbyists have managed to block attempts to regulate the chemicals; some examples are dioxin, BPA, perfluorinated compounds, flame retardants, and additives such as phthalates, although there are many others. When there is public pressure to stop using a specific chemical, there is a history of “regrettable substitution” with chemicals that turn out to be as harmful as the chemical that was replaced.

The fact that the interaction of the thousands of chemicals to which the general population is exposed is not considered, for the relative few (out of an estimated 100,000) chemicals that are tested for health effects, is a major problem that has proven to be very difficult to address in terms of developing experimental protocols that regulatory agencies would be willing to adopt. We thus are

living in the “chemical age” but do not have appropriate safeguards in place to address the findings that environmental chemicals are implicated in many of the chronic diseases, such as obesity and diabetes, and hormone-dependent cancers, that have been increasing since the post World War II dramatic increase in the use of manmade chemicals (Soto et al., 2013; Cohen and vom Saal, 2017; Heindel et al., 2017).

Plastics

Introduction to Plastics

Plastics comprise a diverse group of polymeric materials that can easily be molded and shaped into a variety of different products. Because of their malleable properties, the use of plastics has increased dramatically since it was first introduced on the market a century ago. Especially since the 1950s the annual growth rate has been high, reaching an annual world-wide production of 322 million tons in 2015, corresponding to 43 kg per person (Plastic Europe, 2017). Packaging is the main application for plastics, followed by building and construction materials, automotive parts, electronics, to mention just a few.

Within the food sector, different types of plastic polymers are used. Polyethylenes (PE) and polypropylenes (PP) are among the most common due to their attractive physical and chemical properties, as well as their resistance to moisture. Polyethylene terephthalate (PET) and polycarbonate (PC) are examples of polyesters that are used for disposable bottles suitable for recycling or for nondisposable food and drinking containers, respectively. Polyvinylchloride (PVC) is used to make rigid or cling film, although PE is now the preferred material for cling film since it requires less softener.

Because of the very large world-wide production of plastics, an extremely slow breakdown process, combined with disposable consumer behaviors and a limited fossil fuel reserve, there is a great need for a circular plastic economy. For the most part, the waste management plans are limited or insufficient, which has resulted in a planet literally flooded with plastics. Recycling will make plastic production more sustainable, and reprocessed waste plastic such as multilayer plastic food packaging is expected to be used for many more applications in the future. However, contamination of the recycled products may become very complex and difficult to track and handle. Therefore, alternative bio-based polymers made from nonfossil biomass have been introduced to the markets and are expected to become much more common (Plastic Europe, 2017).

Endocrine Disrupting Chemicals in Plastic

Plastics represent a major source of human exposure to endocrine disrupting chemicals (EDCs). Some of the best known EDCs to which most—if not all—humans are exposed, such as the nonpersistent phthalates and bisphenols, can originate from plastics. Persistent organic pollutants (POPs), such as polychlorinated compounds or brominated flame retardants (BFR), are used in certain nonfood plastic products or are present as nonintentional contaminants and thereby also contribute to the overall exposure burden from plastics.

Plastic polymers have covalent bonds and are therefore not considered likely to migrate from packaging materials to foods or the environment. However, monomers may be present if left unreactive in the polymerization process, as is the case for bisphenols. Furthermore, additives that are not covalently bound to the polymeric plastic material can be added to plastics to improve the physical or chemical properties during production and storage, as well as appearance of the final products. These additives are used as pigments, preservatives, flame retardants or plasticizers.

Substances not covalently bound to plastic polymers can migrate into foods or drinks depending on the physico-chemical properties and concentrations of the chemicals, type of food, contact time and temperature. If the chemicals migrate to the food or are released into the environment, human exposure can occur by the diet, dust, air or dermal contact.

The contents of additives or monomers in food contact materials or migration from these materials are regulated in Europe by the Plastic Regulation 10/2011 (EU, 2011).

Among additives that are allowed in food contact materials, certain preservatives may be of concern for reproductive health. For instance, developmental exposure to the preservatives butylparaben or propylparaben has been shown to affect sperm production in rats, but the general human exposure to parabens originating from plastic is considered very low when compared to other sources, not least cosmetics.

Fact box

<i>Examples of chemicals allowed to be added to plastics, which are either suspected or known to exert endocrine activity</i>	
Bisphenols (monomers)	2,2-Bis(4-hydroxyphenyl)-propan (BPA)
	4,4'-Dihydroxydiphenylsulfon (BPS)
Phthalates (plasticizers)	4-Cumylphenol
	Dibutylphthalate (DBP)
	Benzylbutylphthalate (BBP)
	Bis(2-ethylhexyl)phthalate (DEHP)
	Dimethylterephthalate
	Diallylphthalate
	Dimethylisophthalate
	Diphthalate with primary, saturated C8-C10-alcohols
<i>(Continued)</i>	

Examples of chemicals allowed to be added to plastics, which are either suspected or known to exert endocrine activity

Parabens (preservatives)	Methyl-4-hydroxybenzoate Ethyl-4-hydroxybenzoate Propyl-4-hydroxybenzoate Isopropyl-4-hydroxybenzoate 2,4-di- <i>tert</i> -butylphenyl-3,5-di- <i>tert</i> -butyl-4-hydroxybenzoate
Benzophenons (UV filters)	2,4-dihydroxybenzophenon (benzophenone-1) 4,4'-dihydroxybenzophenon 2-hydroxy-4-methoxybenzophenon 2,2'-dihydroxy-4-methoxybenzophenon 2-hydroxy-4- <i>n</i> -hexyloxybenzophenon 2-hydroxy-4- <i>n</i> -octyloxybenzophenon (benzophenone-12) 4,4'-difluorbenzophenon
Adhesives	Abietic acid

Plastics can enter the aquatic environment as litter or through wastewater. In the aquatic environment the weathering processes can transform plastic materials into microplastics; i.e., plastic particles typically smaller than 5 mm. These may act as vectors for transfer of added or adsorbed chemicals such as chlorinated or brominated POPs to aquatic organisms. These POPs can be highly concentrated on plastic particles due to their high affinity for certain plastics such as PE. In turn, the occurrence of contaminated plastic may affect aquatic organisms, but it is presently unclear if human consumption of fish and seafood leads to exposure levels that may be harmful to humans (Ziccardi et al., 2016).

Phthalates

A wide range of phthalates are used worldwide as additives to plastic materials to soften and make the material more stretchable. Phthalates are used in PVC and PE polymers, where diethylhexyl phthalate (DEHP) has been the most widely used for PVC production so far, but di-*n*-butyl phthalate (DBP), benzylbutylphthalate (BBP), di-isononylphthalate (DiNP), and di-isodecylphthalate (DiDP) are also used. Phthalates are also found in inks, lacquers, and glues for food contact materials (Fierens et al., 2012), in tubing for milk transfer and in numerous applications for nonfood plastics. DEHP, DBP, and DiBP have been shown to be the most abundant phthalate in plastics from household waste and also recycled waste, originating both from plastics and other sources such as adhesives, sealants or inks. However, the use of phthalates is changing over time and the low to intermediate molecular weight ortho-phthalates such as DEHP and DBP are substituted by a range of high molecular weight phthalates, including DiNP and DiDP, as they are currently considered less toxic.

Although the FCM legislation within the EU has set maximum quantities and specific migration limits of different phthalates in plastic for food contact materials, these limits have been exceeded in some cases (Petersen and Jensen, 2016).

Bisphenols

Bisphenol A (BPA) is used in the manufacture of plastics, including PC, polyacrylate, and coatings such as epoxy resins. PC is mainly used to make beverage bottles, infant feeding bottles, tableware (plates and mugs) and storage containers such as water coolers and chocolate molds. BPA-based epoxy resin is used as inner coatings of food cans and lids of glass jars to ensure the preservation of the packaged food. BPA may also be present to some extent in printing inks and adhesives and can migrate in small amounts into food and beverages stored in food contact materials containing the substance. BPA is also used in other consumer products such as thermal paper receipts, toys and medical devices. Thermal paper has been identified as the major source of BPA and bisphenol S in the paper recycling process (Pivnenko et al., 2015).

Due to its adverse effects on human health, BPA is increasingly being substituted by structural analogues such as bisphenol S, E or F. However, several of these have been shown to qualitatively cause the same adverse effects as BPA, making such substitutions problematic (Rosenmai et al., 2014).

Legislation on the presence and migration of BPA from food contact materials varies between countries and regions. United States, European Union, and Canada have prohibited the use of polycarbonate in infant feeding bottles, and specific migration limits have been established for use in other food contact materials.

Persistent Organic Compounds (POPs)

General unintentional contamination of plastics with persistent halogenated compounds is another area of concern for male reproductive health. PVC plastic waste contains chloride which, when incinerated, can release the toxic chlorinated dioxins to the environment unless appropriate filters are applied. Consequently, dioxins can be inhaled by humans, deposited in terrestrial or aquatic environments or biomagnified in the food chain through crops and edible animals. Dioxins, together with chlorinated

biphenyls previously produced in massive amounts for various industrial applications, persist in the environment and accumulate in the food chain.

Brominated flame retardants are added to a wide variety of products such as plastics, textiles and electronic equipment to make them less flammable. But recycling of plastics can potentially reintroduce brominated flame retardants to other food contact materials unintentionally. Among the many types of brominated flame retardants, it is mainly the polybrominated diphenylethers (PBDEs) that have been associated with adverse male reproductive health effects (EFSA, 2011) (Fig. 1).

Chemical Exposure and Effects on Male Reproductive Health

Phthalates

Phthalates are among the most common synthetic chemicals to which humans are exposed. As phthalates are not covalently bound to the plastic, they can leak out of products and enter the environment this way. Oral exposure by ingestion of contaminated foods or dust is considered to be the main route of exposure, but consumer and building products made of plastics may also release phthalates in to the indoor environment, thereby contributing to the overall exposure. Finally human exposure can occur through direct dermal contact with clothes, bags, or toys, but also by using cosmetics. Children are among those highest exposed to phthalates, and infants in neonatal intensive care units that are treated with PVC plastic medical devices containing DEHP, can be significantly exposed.

Certain phthalates have been found to interfere with early male reproductive development by altering fetal germ cell development or inhibiting synthesis of sex steroid hormones. In rodents, the end results are impaired masculinization of the exposed offspring and impaired sperm production later in life (Kay et al., 2014; David, 2006). This is supported by some human epidemiological studies showing associations between maternal exposure to these phthalates and reproductive malformations in their sons (Kay et al., 2014). At high doses, testicular toxicity is also induced with adult exposure. Therefore, DEHP, DBP, BBP, and DIBP have been classified as being reproductive toxicants (ECHA, 2017).

It is generally understood that phthalates with backbones of three to six carbons share similar modes of action when it comes to adversely affecting the reproductive system in experimental animals. These phthalates seem to act via multiple modes of action. Their ability to reduce testicular testosterone production during late gestation in rats is associated with impaired development of androgen-dependent tissues. The exact initiating event is currently unclear, but marked reductions in gene or protein expression

Fig. 1 Various sources of chemical exposure of pregnant women to EDCs such as BPA, phthalates, and POPs are illustrated. If exposure to these male reproductive toxicants occurs during a specific programming window during fetal life, normal development of the male fetus can be disturbed, resulting in male reproductive health disorders such as hypospadias, cryptorchidism or poor sperm quality. The antiandrogenic mode of action is the best described mechanism causing these effects, but other mechanisms may also play a role.

are seen for several steroidogenic factors, including StAR, SR-B1, CYP11A1, and CYP17A1 (David, 2006). In mice, only minor changes in fetal steroid production are seen, whereas changes in early germ cell development are seen in both rats and mice (Albert and Jégou, 2014). Possible species differences have been studied using xenografted human testicular tissues. Xenotransplants of testis tissue from different species appear to respond differently to phthalate exposure with respect to testosterone production, but similarly with respect to germ cell changes. The windows of sensitivity appear to differ between rodents and primates (Albert and Jégou, 2014).

A high number of other phthalates are used as alternatives to the abovementioned phthalates. It is not currently clear whether other phthalates than those with intermediate chain lengths can also adversely affect the male reproductive system. For phthalates with shorter or longer chain lengths, a few human epidemiological studies have found associations between prenatal exposures and anogenital distance, a marker of prenatal androgen insufficiency. Long-chain phthalates such as diisododecyl phthalate (DIDP) and diisononyl phthalate (DINP) are abundantly used, and while DIDP does not appear to influence reproductive function or markers of androgen insufficiency in early life, DINP does seem to affect male reproduction via alterations of testosterone production, though with less potency than e.g., DEHP and DBP (ECHA, 2013). This means that even though the health risk associated with exposure to phthalates from plastics is likely reduced due to current regulations of the most toxic phthalates, the possible impact of other phthalates and alternative plasticizers on male reproductive function is not fully understood.

Bisphenols

The main source of exposure to BPA and other bisphenols is considered to be through foods, but also through the skin by direct contact with thermal paper or by ingestion of dust. Dust seems to be a particular important source for toddlers and young children, who are often playing on floors or chewing on toys that have gathered dust particles.

The potential adverse effects of BPA on human health have been extensively studied over the past decades (Peretz et al., 2014). In the 1940s BPA was identified as being an estrogenic compound, as it was found capable of increasing the size of the uterus. In more recent years, reproductive effects caused by BPA exposure have been a significant focus, culminating in a large body of studies dealing with particularly its endocrine disrupting activity. BPA may act by multiple modes of action including altered steroid production, nuclear receptor interaction and causing epigenetic changes in various tissues.

For regulatory purposes, a large number of studies have been evaluated by different regulatory bodies, including the European Food Safety Agency (EFSA). Based on their extensive review, EFSA concluded that developmental exposure to BPA affects the male and female reproductive system at high doses (EFSA, 2015). The possible influence of developmental exposure at lower doses, however, remains controversial, and EFSA has considered the evidence for male reproductive effects less strong at lower doses. Male reproductive toxicity of BPA at high doses has been seen in several studies in mice and rats evidencing increased incidence of undescended testes at weaning, delayed puberty and reduced sperm quality (Peretz et al., 2014; EFSA, 2015). Other animal studies indicate a role of perinatal BPA exposure in later prostate cancer pathogenesis (Peretz et al., 2014). Collectively, BPA does appear to affect male reproduction, although it is unclear which developmental period is most sensitive, and whether this is only observed at higher doses.

The potential adverse effects of other bisphenols on male reproductive function is less well studied, but several alternatives such as BPB, BPE, BPF, and BPS have shown a similar toxicological profile in vitro (Rosenmai et al., 2014).

Persistent Organic Pollutants

The dioxin 2,3,7,8-TCDD and some PCBs are known to adversely affect sperm parameters in experimental animals exposed prenatally at very low doses. In humans, PCB/dioxin exposure also seems to influence semen quality, leading to increased abnormal morphology and reduced motility. The timing of the exposure is important with prenatal or prepubertal exposure periods being most sensitive (Leijts et al., 2014).

For brominated flame retardants, particularly PBDEs, some evidence exists that they have the potential to disrupt endocrine systems at multiple target sites, and thereby cause adverse effects on male reproductive health. While the thyroid hormone system appears to be the main target of these compounds, recent in vivo studies demonstrated effects on both the estrogen- and androgen-mediated processes (EFSA, 2011). Reproductive and developmental toxicity studies have shown changes in the development of androgen-sensitive male reproductive organs and impaired spermatogenesis following exposure to certain PBDEs (EFSA, 2011), but for many brominated flame retardants there is a general lack of data and knowledge on the possible consequences for human male reproductive function.

Conclusion and Perspectives

Plastics represent an important source of human exposure to chemicals, and of the many potential adverse effects this may cause, male reproductive health is one of them. The most studied and debated endocrine disrupting chemicals, bisphenols and phthalates, originate primarily from plastic materials. From both animal experiments and human epidemiological studies, these chemicals are known to affect male reproductive health. Importantly, most of the health effects that are observed throughout life are believed to arise from exposure during fetal life, the period when the male reproductive system is developing. Based on these findings, the use of

four phthalates, as well as BPA, has been restricted for certain uses within the EU and some other countries. In consequence, these chemicals are now being substituted by structural analogues with differing chain length or small variations in chemical structure. These remain to be investigated in-depth; therefore these substitutions should be used with caution, as evidence exists that chemicals belonging to the same class can often share the same modes of action.

Certain persistent endocrine disrupting chemicals such as brominated flame retardants, PCBs, or dioxins may also be present in plastics, either because they are ubiquitous contaminants in the environment or because they accumulate during recycling, or adhere to microplastics present in the environment.

Although there are specific regulations on plastics used for food contact, humans cannot avoid being exposed to chemicals from plastics. Finally, even though human exposure to each single chemical may be relatively low, the fact that many of them are able to affect male reproductive health makes it conceivable that the combined effects of several chemicals may result in mixture effects among the highest exposed individuals with severe consequences for development of the male fetus.

Glossary

Acceptable daily intake The amount of a substance that can be orally ingested—by foods and drinks—on a daily basis over a lifetime without an appreciative health risk. ADI is expressed in milligrams of substance per kilogram of body weight per day ($\text{mg kg}^{-1} \text{ day}^{-1}$).

Androgens The androgens are any natural or synthetic compound, usually a steroid hormone that can stimulates or controls the development and maintenance of male characteristics in vertebrates by binding to androgen receptors.

Anogenital distance The distance between anus and genitalia. Male AGD is approximately twice that of female in laboratory rodents, as well as humans. The anatomical region is called the perineum and develops differently between the sexes by way of androgen stimulation during fetal life in males, but not in females.

Cryptorchidism The absence of one or both testes from the scrotum. The condition can be caused by undescended testis, but also ectopic, atrophic or absent testis. It is the most common reproductive birth defect in males.

Endocrine disruptors An endocrine disruptor is an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub) populations. A potential endocrine disruptor is an exogenous substance or mixture that possesses properties that might be expected to lead to endocrine disruption in an intact organism, or its progeny, or (sub) populations.

Hypospadias A condition where the opening of the urethra is not located at the tip of the penis, but somewhere along the underside of the penile shaft between the penis head and the scrotum.

Pesticides A pesticide is any substance intended to repel, mitigate, or kill pests. Depending on their target organism, pesticides are typically grouped into different classes: insecticides are used against insects; herbicides (or weed-killers) are used against unwanted plants; fungicides are used against molds or fungi; rodenticides are used against mammals, typically mice and rats; and antimicrobials are used against microorganisms such as bacteria and viruses.

Abbreviations

ADI Acceptable daily intake
AGD Anogenital distance
AMH Anti-Müllerian hormone
AR Androgen receptor
DHT Dihydrotestosterone
E Embryonic day
EDC Endocrine disrupting chemical
FSH Follicle stimulating hormone
GW Gestational week
LH Luteinizing hormone
PCB Polychlorinated biphenyl
SHBG Sex-hormone binding globulin

Introduction

Pesticides are substances used to control or kill pests. A pest, in turn, can broadly be defined as any living organism that is either a nuisance or detrimental to human health, or that can have negative impact on human interests such as agriculture and livestock production. Pesticides thus comprise a broad range of substances with varied biological effects, but have in common that they often interfere with essential biological functions of the target organism. Because living organisms share many biomolecular processes, pesticides are rarely specific to just one species. While a pesticide may effectively harm or kill their intended target, the same pesticide may inadvertently also harm other organisms, including humans.

Humans are exposed to many different pesticides from various sources. This includes occupational exposure, consumption of foods containing pesticide residues, by use of domestic herbicides and insecticides, or by contact with contaminated water or air. If

the biological effects for which the pesticides were selected for can also affect humans, exposure can have detrimental consequences. The resulting adverse effects will in turn depend on different parameters such as level and timing of exposure, or mechanisms of action. In this article we will focus on potential effects on the male reproductive system, many of which are believed to arise from exposure during fetal life.

Androgen Signaling and Male Sexual Development

Sexual development is a complex process that involves several key steps that takes place sequentially from early fetal life to puberty. This ensures the development of two sexually mature phenotypes, male and female, which is necessary for procreation. This is a very complex subject and beyond the scope of this article, but additional information can be found in other articles. However, some key points need to be addressed and understood in order to grasp how pesticides potentially can affect male reproductive health.

Firstly, male and female embryos initially develop similarly and are morphologically indistinguishable from each other until testicles or ovaries have formed. This event, referred to as gonadal sex determination, is initiated at around gestational week (GW) 6 in humans, but midway through gestation in mice and rats, starting at around embryonic day (E) 10 and 12, respectively. The differentiation of the gonads into testicles or ovaries is independent of sex hormones, and instead relies on the timely expression of certain sex-determining genes (Svingen and Koopman, 2013). It is after the gonads have differentiated that the development of the rest of the body also starts to diverge between the sexes. In simple terms, the fetal testicles will start to produce various hormones that will influence the differentiation of other cells and tissues throughout the body so that they develop into male tissues and organs. For instance, the production of anti-Müllerian hormone (AMH) will cause the regression of the Müllerian ducts, hence preventing the female reproductive tracts to develop, but promote the development of the male reproductive tracts from the Wolffian ducts. Production of the main male sex hormone testosterone together with other androgens will stimulate peripheral tissues—primarily through the Androgen receptor (AR)—to differentiate into male phenotypes. In contrast, it is the absence of androgens (in other words; ovaries, rather than testicles) that ensures female development.

Since proper masculinization of the fetus depends on androgens produced by the testicles, male sexual development is particularly sensitive to endocrine disruption during these critical periods. Endocrine disrupting chemicals (EDCs) with antiandrogenic properties are believed to be of particular concern, since they can block normal androgen function either by reducing the amount of available testosterone or by interfering with the AR. Exposure to antiandrogenic compounds during pregnancy can therefore result in undervirilized, or feminized, offspring. The question then is, do pesticides have endocrine disrupting properties and if yes, can they be detrimental to male reproductive health? Fig. 1

Pesticides as Endocrine Disruptors

Pesticide exposure has been linked to endocrine disruption and consequently, with reproductive health issues (Mnif et al., 2011). The type of adverse effects is dependent on several factors, especially the type of pesticide, the dose level of the pesticide(s), and the

Fig. 1 Examples of pesticides that can interfere with male reproductive development. The testicular Leydig cells are responsible for the production of testosterone. The process by which cholesterol is converted into sex steroid hormones is referred to as steroidogenesis; a multistep pathway involving several key enzymes. Testosterone is secreted from the testicular Leydig cells. In many peripheral tissues, 5 α -reductase converts testosterone into DHT, a powerful androgen that can bind to and activate the AR. In turn, activated AR translocates to the nucleus of the cells and activates gene expression by directly binding to DNA. Some pesticides can interfere with activation of AR itself, or with various steps involved in androgen synthesis or metabolism, which can ultimately disrupt masculinization of the fetus.

Table 1 Examples of pesticides reported to cause effects on male reproductive health

<i>Pesticide</i>	<i>Pesticide class</i>	<i>Possible adverse effects</i>
Carbaryl	Insecticide	Reduce sperm counts and motility
Chlordecone	Fungicide and insecticide	Reduce sperm counts and motility
Linuron	Herbicide	Disrupts Leydig cell steroidogenesis. Shorter AGD in rats.
Mancozeb	Fungicide	Various effects in rodents including: reduced sperm counts, toxic effects on testis, suppressed testosterone levels
Prochloraz	Fungicide	Interacts with nuclear receptors such as AR and ER. Nipple retention, reproductive malformations, reduced testosterone levels in rats
Procymidone	Fungicide	Inhibits AR activation. Multiple reproductive malformations, including nipple retention, shorter AGD, hypospadias, and cryptorchidism
Vinclozolin	Fungicide	Inhibits AR activation. Multiple reproductive malformations, including nipple retention, shorter AGD, hypospadias, and cryptorchidism

time of exposure. With regards to male reproductive health, it is the fetal period that is of particular concern. The causative molecular mechanisms can be quite diverse, and many pesticides are also known to affect more than one molecular pathway (e.g., AR antagonism, induction or inhibition of aromatase activity, affecting steroid hormone production). The most common modes of action with regards to endocrine disruption include antiandrogenic effects, estrogenic and antiestrogenic effects, disruption of aromatase activity, or estradiol or androgen production. Disruption of thyroid hormone action and interference with steroid hormone metabolism have also been reported (Mnif et al., 2011).

Organochlorine pesticides and conazole fungicides have been linked to adverse male reproductive health effects. From studies involving laboratory animals or wildlife, as well as human epidemiological studies, these pesticide classes are believed to affect the steroid hormone balance in organisms by various mechanisms, ranging from binding to various hormone receptors, disruption of hormone synthesis, or effects on metabolism. In the following section, we will highlight a handful of pesticides and discuss what effects they may have on the male reproductive system in laboratory animals. This information is also summarized in Table 1.

Animal Studies

Pesticides can affect the endocrine system of different animal species, ranging from invertebrates to reptiles, fish, birds, and mammals. Since sexual development varies significantly between distant animal taxa, we will focus on mammals, more specifically mice and rats, in this article. Furthermore, intrauterine exposure is the main focus, since it is during fetal life that male fetuses are particularly sensitive to endocrine disruption. In other words, in utero exposure experiments can best forewarn us about what effects maternal exposure can have for the future reproductive health of the male offspring.

It is now clear that exposure to endocrine disrupting pesticides during fetal and prenatal life can adversely affect male reproductive development. The most common effects readily observed at birth include shorter anogenital distance (AGD), retained nipples, cryptorchidism and penile malformations, typically hypospadias or cleft phallus. There are also proposed late-life effects such as reduced fertility. Below, we will describe four pesticides for which there is clear evidence that they can adversely affect male reproductive development in rodents.

Linuron is a selective organochlorine herbicide used to control broadleaf and grassy weeds for crops such as carrots, beans, and peas. When administered to pregnant rats, the male offspring show a significantly reduced testosterone production (Wilson et al., 2009). Linuron appears to directly affect Leydig cell steroidogenesis by suppressing the expression of key enzymes, leading to low testosterone levels in the male fetus, and ultimately significantly shorter AGD than normal (McIntyre et al., 2002). In other words, exposure to linuron during the male masculinization window prevents the fetus from masculinizing properly, resulting in feminization phenotypes at birth and potential reproductive health issues later in life.

Vinclozolin is a fungicide commonly used in vineyards, but also for the protection of other fruit and vegetable crops, albeit now banned in some countries. It acts by inhibiting spore germination and mycelial growth in fungi. It is the metabolites of vinclozolin, M1 and M2, that can bind to the AR and prevent binding to DNA, ultimately inhibiting androgen-dependent gene expression. Following fetal exposure to high doses of vinclozolin, male rat offspring are born with a significantly shorter AGD, resembling the distance in female rats. They also often present with retained nipples, cleft phallus with hypospadias, cryptorchidism, vaginal pouch, epididymal granulomas, and small to absent sex accessory glands (Gray et al., 1994). So again, the end result of exposure is undervirilization of the fetus, but by different mechanisms of action than what was the case with linuron.

Procymidone, like vinclozolin, is a dicarboximide fungicide widely used as a seed dressing and for the general control of fungal diseases pre- and postharvest. Procymidone looks to display a nearly identical toxicity profile as vinclozolin, both in vitro and in vivo, albeit with lower potency. It is also an AR antagonist. In rats, perinatal exposure to procymidone can lead to shorter AGD, increased nipple retention, hypospadias, cryptorchidism, as well as reduced prostate, testis and epididymal weights (Ostby et al., 1999).

Prochloraz is an imidazole fungicide used to protect a wide range of crops such as cereals and fruits. In rats, high-dose exposure during fetal life can adversely affect several organ systems by various mechanisms of action (Vinggaard et al., 2005). A common feature of azole fungicides is their propensity to affect steroid hormone levels in pregnant rats and their fetuses, as well as prolonging the gestational period. Male offspring that have been exposed in utero to prochloraz often display nipple retention (Christiansen et al., 2009; Vinggaard et al., 2005), whereas effects on AGD are conflicting. The effects are believed to be the result of reduced intra-testicular and plasma testosterone levels caused by prochloraz interfering with steroidogenesis (Laier et al., 2006).

From these four examples, it is clear that that some pesticides can disrupts male sexual development by interfering with androgen signaling, at least in rodent models. Notably, the adverse effects are typically seen at relatively high dose levels. Humans are rarely, if ever, exposed to such high doses, so the question remains if humans are at real risk from exposure to pesticides. Although a topic of debate, one possible way in which humans can be put at risk is through a combined exposure to a large number of different pesticides and other environmental chemicals with similar modes of action. There are literally hundreds of pesticides of various chemical classes currently in use, but tens of thousands of environmental chemicals more broadly. This scenario is commonly referred to as the “mixture,” or “cocktail effect,” whereby single chemicals that are present at doses that alone does not elicit an effect, can cause adverse effects in combination when many chemicals with similar mechanisms of action are present at the same time. A clear example of this has been shown in rat studies where in utero exposure to five pesticides combined can cause significant effects at doses where the pesticides give little or no effect alone (Hass et al., 2012). There are also indications that cumulative exposure to EDCs can affect human development, with epidemiological studies reporting associations between organochlorine pesticides and congenital cryptorchidism (Damgaard et al., 2006). But to get an understanding of any potential risk, human exposure data must also be obtained and analyzed.

Human Epidemiological Studies

Pesticides with endocrine disrupting properties have been associated with disrupted reproductive development in humans. Also, as is the case for animals, fetuses, and infants are more vulnerable to exposure than adults, since much of the damage caused by EDCs take place during critical stages of fetal life (Mnif et al., 2011). A higher prevalence of cryptorchidism and hypospadias in newborn boys has been observed in areas with extensive farming and pesticide use, as well as in sons of women that work in greenhouses (Kristensen et al., 1997; Weidner et al., 1998). A relationship has also been reported between cryptorchidism and persistent pesticide concentration in maternal breast milk (Damgaard et al., 2006).

A meta-analysis of human epidemiological studies found that pesticide exposure may affect spermatogenesis, leading to poor semen quality and reduced male fertility, as well as a possible link to prostate cancer (Mnif et al., 2011). Notably, the former conditions are often linked to antiandrogenic effects, whereas for instance prostate cancer has been associated with exposure to pesticides with estrogenic properties, as for instance chlordecon (Kepone), an insecticide previously used heavily in banana crop protection (Multigner et al., 2010). In many ways, chlordecon stands out as a clear example where heavy and prolonged pesticide use can have deleterious effects on male reproductive health, shown by a string of studies carried out on the populations in the French West Indies where chlordecon was intensively used on banana crops from around 1973 to 1993 (Multigner et al., 2016).

Despite some incidences, individual pesticides are by themselves generally not believed to cause adverse reproductive health effects in humans at exposure levels relevant for the general population. However, some studies suggest an increased prevalence of cryptorchidism, decreased penile length, and testicular size in sons born from women working as gardeners or living on farms where pesticides have been used (Andersen et al., 2008). In particular, female greenhouse workers had an increased risk of delivering boys with classic symptoms of disrupted fetal masculinization programming, including cryptorchidism, smaller penis or testicles, lower serum concentrations of testosterone and inhibin B, higher serum concentrations of SHBG and FSH, or a generally higher LH:testosterone ratio (Andersen et al., 2008). Taken together, these data all point in a direction where certain pesticides can disrupt normal androgen signaling during fetal life, whereupon the male fetus fail to masculinize properly.

Beyond disrupted fetal development, there are also examples where pesticide exposure can adversely affect the reproductive health of adult men. For instance, 1,2-dibromo-3-chloropropane (DBCP) is a classic example of a man-made chemical (pesticide) that affects spermatogenesis. Historically, DBCP was used as a soil fumigant to control nematode worms. Several animal studies have shown effects on the testicles, particularly on sperm quality, but also that DBCP is a water-soluble and persistent chemical that lingers on in the environment. Several years after it was discovered that men had been occupationally exposed to DBCP, their sperm counts were either zero, or so low that it rendered the men sterile (Pryor et al., 2008).

Pesticide Exposure and Consequences for Male Reproduction

The average person is generally exposed to very low levels of pesticides, much lower than what is the case with many other chemicals. However, some people may be exposed to greater levels, especially those who regularly work with pesticides, for instance in greenhouses or farmland. This is evident in that most epidemiological studies that show associations between male reproductive disorders and pesticide exposure have been conducted on gardeners or farmers. For the general population, the risk of developing

reproductive health issues from exposure to single pesticides would be considered low, if not negligible. In fact, pragmatic acceptable daily intake (ADI) calculations—typically derived from rodent experiments—suggest that humans are at low risk from exposure to either single pesticides, or combinations of pesticides. It should be noted, however, that the ADIs are derived from animal data and that there are indications that humans may be more sensitive toward pesticide exposure than rodents. Especially, epidemiological data from the general human population have shown associations between neurological disorders and some pesticides, indicating a discrepancy between animal-derived ADIs and actual risk to humans.

As a final note; when evaluating the potential risk of chemical exposure, it is not sufficient to simply evaluate exposure to single chemicals. The combined exposure of all chemicals, being it pesticides or any other type of environmental chemical, must be considered together as a mixture. Humans are exposed to a large number and variety of chemicals at any given time, and will typically include chemicals such as phthalates, bisphenols, PCBs, dioxins, and so forth, all of which have the potential to affect male reproductive health parameters. Therefore, although pesticides alone may be of less concern, they could become a concern if contributing toward the total load of endocrine disrupting compounds, ultimately putting the male reproductive system at risk.

Glossary

Acrosome reaction An exocytosis event in which the sperm outer acrosomal membrane and the sperm plasma membrane fuse at multiple sites, leading to the release of hydrolytic enzymes and to the exposure of new membrane domains, both of which are essential for fertilization to occur.

Capacitation Fertilizing competence acquisition where spermatozoa undergo a series of poorly understood maturation steps that include increased plasma membrane permeability and fluidity due to cholesterol efflux, influx of ions specially Ca^{2+} and bicarbonate (HCO_3^-), internal pH rise and protein phosphorylation, typically on tyrosine residues.

Cryptorchidism Genital abnormality characterized by the absence of one or both testes in the scrotum. Commonly referred as undescended testis.

Endocrine-disrupting chemical or endocrine disruptor (EDC) Man-made or naturally occurring substance that can mimic natural hormone activity at different levels.

Hypospadias Congenital disorder in which the opening of the urethra is located on the underside of the penis, instead of on the tip.

Spermatozoon/sperm Male haploid cell that has resulted from the process of spermatogenesis. Male sexual cell responsible for the delivery of the paternal DNA to the oocyte.

Testicular dysgenesis syndrome A proposed hypothesis in which poor semen quality, testicular cancer, cryptorchidism, and hypospadias result from errors during the development of the fetal testes. Therefore, as they share a common origin, these different aspects should be recognized as a single syndrome.

What Are Endocrine Disruptors (EDCs)? Context and Sources of Exposure

Published in 1992 a pioneer study involving a group of men with no history of infertility highlighted a decrease in both sperm concentration and mean semen volume, and a concomitant reduction in total sperm count over a 50-year period. Since then, a considerable amount of papers, including an extensive study published in 2017, has reported diminished (and still declining) human sperm quality and increasing trends of testicular cancer and anomalies in male reproductive organs, such as cryptorchidism and hypospadias, over the last decades in several areas of the world, thus jeopardizing male reproductive health. Indeed, this type of evidence led Skakkebaek and colleagues to propose that all these conditions are part of one single underlying issue—the testicular dysgenesis syndrome (TDS). The authors hypothesized that these abnormalities originate from specific errors that take place during fetal testes development. Given that this developmental origin is common, they should thus be recognized as a single entity, the so-called TDS, although it is obviously acknowledged that different individuals might display distinct severities. This proposal was based on the understanding that variations in fetal hormone levels may affect the development of the male reproductive tract, and that hormone-mimicking compounds in the environment could possibly play a role in disturbing this intricately regulated process.

Although it has not been widely accepted, the worrying increase in male reproductive tract anomalies and poor sperm quality does suggest that exposure to environmental factors, such as endocrine-disrupting chemicals (EDCs) might be, at least in part, responsible for these outcomes. EDCs are an extremely heterogeneous group of compounds that include man-made substances such as polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), pesticides, phthalates, alkylphenols, bisphenol A (BPA), diethylstilbestrol (DES); and naturally occurring compounds, such as phytoestrogens and mycotoxins. By definition, these compounds can mimic endogenous hormones, and promote endocrine imbalance via different mechanisms of action. Thus, by interfering with hormone synthesis, binding and/or action, EDCs can potentially disturb the normal development and function of tissues and organs, and the male reproductive system does not seem to be an exception. Indeed, it has been broadly argued that by presenting (anti)estrogenic- or antiandrogenic-like activities EDCs are likely to affect male reproductive health and fertility, in both human, animal and wildlife populations.

Populations are continuously exposed to EDCs due to their widespread use and high persistency in the environment. Even the restriction or ban of several persistent organic pollutants—including PCDDs, PCBs, PAHs, and several pesticides—in many countries (as agreed in the Stockholm Convention), did not necessarily spare these populations, given the strong resistance of many of these compounds to degradation. EDCs are present in our daily lives, and we are exposed mainly through diet, although dermal contact and inhalation may also contribute. Moreover, given their lipophilic nature, persistent organic pollutants may bioaccumulate in the food chain, since they can be stored in body fat for extended periods. This implies that species on the top of food chains are especially susceptible, given that they can be exposed both directly, and via ingestion of contaminated food sources

that have previously accumulated EDCs. Other EDCs, such as phthalates and BPA, do not accumulate in the body, but chronic exposure to low levels via dietary intake and commonly used products can provide continuous steady state doses in living organisms that may produce undesirable effects.

Additionally, as an obvious consequence of exposure, EDCs and/or their metabolites can be found not only in body fluids such as urine, blood serum or breast milk, but many can also be detected in reproductive fluids, including seminal fluid, cervical mucus, and female reproductive tract secretions. This is an important route of exposure that should not be overlooked, as spermatozoa steep in these fluids/secretions on their journey toward the oocyte, thus coming into direct contact with these compounds with possible deleterious consequences. Indeed, it is known that EDCs may act both through genomic and nongenomic hormone-independent pathways (e.g., by affecting ion channels and signaling pathways) causing a wide spectrum of effects on male reproductive function, ultimately compromising sperm fertilizing ability, and thus jeopardizing male fertility.

In general, whether they persist in tissues and body fluids or are rapidly excreted by the organism, continuous exposure to EDCs may threaten the reproductive health status of both human and animal/wildlife populations. Furthermore, in accordance with the United Nations Environment Program "Endocrine Disrupting Chemicals" and the 2013 report of the World Health Organization (WHO), nearly 800 substances are recognized as supposedly able of disturbing the endocrine system, and only a limited number of these substances have been studied. With more and more compounds being produced daily, for example, to replace certain pesticides or other dangerous chemicals, the numbers are increasing. A nonexhaustive list of some of the major compounds described as EDCs relevant for male fertility is shown in Table 1, and their prevalence constitutes a serious public health issue that should not be neglected.

This article intends to briefly summarize the effects of EDCs on male reproductive function, integrating both epidemiological and experimental evidence. Special emphasis was placed on effects related to sperm quality and function.

Epidemiological and Experimental Data: An Overview

An increasing number of reports have documented the effects of several EDCs, in many cases using laboratory animals as a strategy to (cautiously) infer about putative human exposure effects. Others have been studying the impact of EDCs in commercially valuable species and in wildlife. Understandably, studies with humans can only involve: (1) epidemiological data; or, (2) in vitro experimental settings in which human cells (including spermatozoa) are exposed to different concentrations of distinct compounds for precise amounts of time. In addition, the epidemiological strategy may include an analysis of both populations with high exposure episodes (industrial accidents, areas with a heavy use of pesticides) or high dietary intakes (the consumption of foodstuffs with high levels of EDCs); and populations with no obvious exposure to EDCs, that are often enrolled when undergoing routine semen analysis and/or seeking assisted reproduction treatments (which can constitute a sampling bias).

Reproductive abnormalities such as altered anogenital distance, nipple retention, modifications in the structure and function of the testis and other reproductive organs have been attributed to EDC exposure in animal models and, in wildlife, the most notorious cases are possibly the egg shell thinning in birds, and the poorly organized testis and abnormally small phalli of male juvenile alligators in contaminated areas.

Although with some exceptions, possibly due to the different concentrations found in urine, seminal or blood serum samples, exposure to EDCs in men has been associated with a reduction of the sperm parameters monitored using standard WHO criteria, namely sperm concentration, motility, and morphology. Sperm motility is of obvious importance for fertilization in vivo, and it has been shown to be affected by a vast range of EDCs, not only in humans but also in rodents, rabbits, boar/pig and horse, as shown by many in vivo and in vitro studies using different experimental approaches, doses and times of exposure. Similarly, the functional status of sperm mitochondria, which is correlated with sperm fertilizing ability, seems to be a target of EDCs. A reduction in sperm antioxidant scavenging defenses and/or a rise in the production of reactive oxygen species (ROS) have also been observed following EDCs exposure, not only in human male gametes but also in sperm from other species. This may potentially lead to downstream complications, such as DNA fragmentation, lipid peroxidation and apoptosis, all of which have been reported to occur at least in an in vitro scenario of exposure. Furthermore, although not extensively addressed, sperm capacitation in vitro is affected after treatment with a putative environmentally relevant EDC mixture containing mainly PCBs and pesticides. Because prematurely acrosome-reacted sperm cannot fertilize the oocyte, several EDCs could also provoke undesirable effects on male fertility given their ability to interfere with the acrosome reaction. Other studies have also shown reduced sperm energy status and inhibition of fertilization rates due to EDC exposure. Moreover, the discovery that many (but not all) EDCs are able to interfere with sperm plasma membrane channels such as CatSper (a calcium ion channel), and disturb normal cytoplasmic ion concentrations that are relevant to both capacitation and the acrosome reaction, add further evidence to the potential adverse of these compounds on male reproductive health. Importantly, recent data clearly shows that concentrations of EDCs that can cause sperm dysfunction are physiologically and environmentally relevant, thus preemptively answering possible criticism in terms of doses used in vitro being considered unrealistic for in vivo situations.

Reports using sperm samples collected from human populations frequently lack the evaluation of functional parameters that more accurately reflect male fertility, in comparison with the standard WHO parameters. However, to some extent they give similar results to what was obtained in vitro. For instance, studies on *p,p'*-dichlorodiphenyl dichloroethylene (*p,p'*-DDE), the major and most stable metabolite of the pesticide dichlorodiphenyl trichloroethane (DDT) sprayed in dwellings as a way to control malaria-bearing mosquitoes in some countries, have been shown to adversely affect human reproductive outcomes. In these

Table 1 Some compounds known for their endocrine-disrupting properties in male fertility

<i>EDCs</i>	<i>Examples</i>
Polychlorinated dibenzo- <i>p</i> -dioxins (PCDDs)	TCDD
Polychlorinated biphenyls (PCBs)	PCB 54
	PCB 77
	PCB 153
	PCB 118
	Aroclor 1254
Polycyclic aromatic hydrocarbons (PAHs)	B[a]P, BPDE
Pesticides	Alachlor
	β -HCH
	Lindane
	DDT and related metabolites (e.g., <i>p,p'</i> -DDD, <i>p,p'</i> -DDE)
	Methoxychlor
	Vinclozolin
	Chlorpyrifos
	Deltamethrin
	Dimethoate
	Permethrin
	Cypermethrin
	Atrazine
	Fenoxapropethyl
	Diazinon
	Malathion
	Bendiocarb
	Endosulfan
	Parathion
	Paraoxon
	Flutamide
	DBCP
Phthalates	2,4-D
	DBP
	DEP
	DMP
	DOP
	DEHP
	DBP
	DEHP
	DnBP
	BBzP
	DiBP
	DPP
Alkylphenols	Nonylphenol, octylphenol
Bisphenol A (BPA)	
Diethylstilbestrol (DES)	
Phytoestrogens	Genistein, daidzein
Mycotoxins	Aflatoxin B1
	ZEA
	α -ZOL
	α -ZAL
	β -ZOL

Dioxins: TCDD, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin; *micotoxins*: ZEA, zearalenone; α -ZOL, α -zearalenol; β -ZOL, β -zearalenol; α -ZAL, α -zearalanol; *pesticides*: β -HCH, β -hexachlorocyclohexane; PCB54, 2,2',6,6'-tetrachlorobiphenyl; PCB77, 3,3',4,4'-tetrachlorobiphenyl; PCB153, 2,2',4,4',5,5'-hexachlorobiphenyl; PCB118, 2,3',4,4',5-pentachlorobiphenyl; 2,4-D-, 2,4-dichlorophenoxyacetic acid; DBCP, 1,2-dibromo-3-chloropropane; *phthalates*: BBzP, benzyl butyl phthalate; DiBP, di-*isobutyl* phthalate; DnBP, dibutyl phthalate; DPP, dipentyl phthalate; DBP, dibutyl phthalate; DEP, diethyl phthalate; DMP, dimethyl phthalate; DOP, dioctyl phthalate; DEHP, di(2-ethylhexyl)phthalate.

Please note that this list is not exhaustive, it merely indicates the major classes that comprise the wide and heterogeneous group of EDCs and associated compounds. See text for discussion.

populations, semen volume, sperm count, concentration, motility, morphology, and chromatin integrity were inversely correlated with *p,p'*-DDE levels in serum of men exposed to extremely high DDT and *p,p'*-DDE concentrations. However, opposing reports have shown no correlations between *p,p'*-DDE serum concentrations and reproductive hormone levels or standard sperm parameters and chromatin/DNA damage in different populations. But, although *p,p'*-DDE was considered elevated in these populations,

due to a high intake of contaminated food, it was at least 1000-fold lower than the levels reported in individuals from malaria-endemic regions, possibly justifying the different outcomes. Furthermore, increasing levels of the EDC 2,2',4,4',5,5'-hexachlorobiphenyl (PCB 153), frequently used as a proxy for the total PCB body burden, have been correlated with decreased chromatin/DNA integrity in European men.

In addition, many other studies have raised important concerns. For instance, the exposure to what is believed to be the most powerful toxic agent ever made by mankind—2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)—was found to exert a broad spectrum of effects, including decreased sperm count, reduced reproductive organ weights, altered hormone levels, and altered urogenital features (e.g., anogenital distance) in many studies, suggesting that the male reproductive system is a TCDD-sensitive target *in vivo*. However, data in humans is scarce, and most of the understanding regarding TCDD effects comes from studies carried out with the population of Seveso (Italy) following an explosion that released high amounts of TCDD into the environment. Of note, breast-fed sons whose Seveso mothers presented a low median serum dioxin concentration at conception have lower sperm counts, concentration and motility and altered serum hormone levels, showing that *in utero* and lactation exposure of children to reasonably low TCDD concentrations can permanently decrease sperm quality. Strikingly, even 22 years after exposure men exposed to TCDD during childhood presented abnormal sperm concentration, motility and hormone levels, while men exposed only during puberty or adulthood showed an increase in these parameters, or no differences relative to controls. However, exposure during either infancy or puberty led to a permanent alteration of hormone levels, such as those of FSH and estradiol. These long-lasting endocrine changes were observed at serum TCDD doses within one order of magnitude of what was determined in the 1970–80s in modern countries, leading to the premise that the reported decrease in sperm quality, principally in younger men, could be partially attributed to TCDD exposure.

Finally, recent reports have suggested a completely new mechanism of EDC action that involves the potential transgenerational inheritance of effects. So far, studies performed in rodents have suggested that exposure to EDCs during gonadal sex determination may lead to a reprogramming of the male germline, not only leading to detrimental effects in the F1 generation but also inducing a transgenerational effect up to the third or fourth generation (F3 or F4) without additional exposure besides the initial F0 pregnant dam, in essence signifying that great-grandparents may transmit unwanted characteristics to their male descendants. Although some high doses were employed in these studies, and strain-specific effects have been reported, the hypothesis is that EDCs may alter the programming of the male germline. This will possibly transmit an altered epigenome in an imprinted-like manner across generations, thus inducing adult onset diseases, such as testis pathologies and a reduced fertilizing capability phenotype, emphasizing that male subfertility might be maintained throughout many generations. However, it is still to be determined whether this effect might also take place in humans.

Conclusions

The data currently available shows that several EDCs may induce impairments in male reproductive function, ultimately contributing towards an increase in male infertility/subfertility. Whether acting via genomic or nongenomic signaling pathways, many EDCs may compromise sperm quality and function during (1) testis and male reproductive tract development; (2) spermatogenesis; (3) storage/transit through the male reproductive tract; and/or (4) in the female reproductive tract. In general, EDCs may not only affect sperm production, motility, mitochondrial function, oxidative status, and/or DNA integrity but also capacitation and sperm ability to undergo the acrosome reaction and fuse with the oocyte, among other possible effects, and this will necessarily be reflected on fertilization success.

However, it is also important to note that some studies have used EDC concentrations that are far higher than what populations are normally exposed to, and higher than what is detected in body tissues and fluids. Although this may be crucial in order to unveil the molecular mechanisms of action underlying EDC toxicity, the relevance in an environmental context may be questioned. The only exception might be the cases in involving heavily contaminated scenarios (such as in the Seveso disaster, the Yucheng contamination, or in malaria-endemic areas, among others). These populations were accidentally exposed to extremely high levels of certain EDCs, but little is known about the resulting levels of these compounds in reproductive fluids and secretions, although it is expected to be higher than in other populations.

Importantly, although recently physiologically and environmentally relevant EDC concentrations have already been shown to have potential deleterious effects, currently available studies tend to focus on the effects of an individual EDC and not many pay attention to mixtures, which represent the truly relevant situation. In fact, human and animal populations are simultaneously exposed to numerous EDCs, and there is limited information on the putative synergistic effects of such compounds on male reproductive function, an issue that should be taken seriously into consideration in forthcoming years. Indeed, when acting together lower concentrations of EDCs may be needed to promote undesirable effects, making the environmentally relevant EDC concentrations more threatening than what might have been anticipated solely from *in vitro* data using single compounds.

Finally, it is also important to keep in mind that a key aspect that may lead EDCs to affect human and animal/wildlife populations in some contexts, but not in others, may be related to when the exposure takes place. Indeed, besides the concentrations used, duration and routes of exposure, or individual EDCs versus mixtures, many studies show that future male reproductive capacity may be more affected if the organism is exposed during critical windows of development, such as during fetal development and the early postnatal period. The data available also suggests that deleterious changes in male reproductive function may be more severe, even permanent, during these time periods, when compared to instances of exposure in adulthood.

Glossary

Epigenetic modifications Accessory chemical modifications of the DNA that are mitotically stable and able to regulate gene expression and post-translational processes.

Epigenome Set of all epigenetic modifications found in a given genome.

Endocrine disruptor An exogenous substance that mimic the action of endogenous hormones on organisms.

Transgenerational epigenetic inheritance Process of inheritance in which environmental exposures modify the epigenome of the gametes, which will consequently influence the phenotype formation in the descendants. Heritable changes are observed in an unexposed offspring as consequence of parental exposure to environmental insults.

DNA methylation An enzymatic chemical reaction in which CH₃ (methyl) groups are covalently added to nucleotides, preferentially cytosines neighboring guanines (direction 5' to 3'); these dinucleotides are known as CpG sites.

Histone Protein directly involved in the structural compaction of DNA, which regulate the access of transcription factors to the genome, and consequently gene expression and post-translational processes.

ncRNA Small RNA molecules;(e.g., miRNAs, tRNAs, piRNAs) that are not translated into proteins, but that are able to regulate gene expression and post-translational processes.

Reprogramming Depletion and re-establishment of epigenetic marks, which occurs at different developmental windows.

Introduction

When we think of reproduction, what generally comes to mind is sexual intercourse with the union of gametes and the consequent generation of a new individual. However, even though these are important aspects, reproduction is much more than the action of hormones, sexual coupling or the generational transfer of genes. Reproduction, which depends on both intrinsic and extrinsic factors, can be defined as the parents passing to the progeny both structural (e.g., molecules, cellular compartments) and environmental features involved in the emergence of a living organization (Maturana-Romesin and Mpodozis, 2000). Simply put, reproduction involves parents perpetuating genes (among other chemical structures), and the maintenance of the parental environment involved in reproductive events. Therefore, the environmental context plays a fundamental role in the process of reproduction.

The question of how an adult organism unfolds after the merging of two gametes have been around since Aristotelian time. Adherents of “preformation” answered this question by stating that all the components needed for the embryo to become an adult individual were already inside the gametes. On the other side of the spectrum, those supporting “epigenesis” thought that gametes and embryonic cells needed to interact with external signals in order to generate an adult individual.

The concept of epigenesis had vital importance in forming the field of “epigenetics.” The term “epigenetics” was firstly introduced by Conrad H. Waddington, a British Geneticist, in 1942 in his paper “The Epigenotype,” before DNA and the molecular machinery of gene expression were described. Waddington asked “how genes interact with their products and the environment to bring phenotypes into being?” By combining the term “epigenesis” and “genetics” he came up with a term that is now becoming highly important in all fields of biological sciences: “Epigenetics.”

One of the main aspects of epigenetics is to see the genome as a reactive chemical entity rather than as a “code” directing the development of organisms towards an adult phenotype. This is because behind the A, C, G, and T letters of this so-called “genetic code,” there is an enormous complexity: the one inherent to every chemical structure.

Just as lipids or proteins, the DNA has a molecular structure, and as such, it interacts with an array of other molecular structures. These can be proteins such as histones, small fragments of RNA or simply methyl groups that attach to the DNA structure and block or modify the translation of parts of the genome. When such interactive modifications with the DNA are maintained even after cell divisions, they are defined as “epigenetic” modifications, with a remarkable feature: not only can they regulate gene expression, but can be influenced by environmental cues.

A major breakthrough in epigenetic research is the ability to understand the etiology of diseases for which genetic associations have never been found, or where these only explain a limited number of cases. By focusing on environmental exposures during early development, and the epigenetic changes they produce, we can start to understand the causes and mechanisms of many diseases of common and increasing occurrence. Early developmental exposures and epigenetic changes are nowadays correlated with an array of pathologies, which includes metabolic syndrome, cardiovascular diseases, allergies or different types of cancer.

Recently, evidence has even shown that environmental exposure during pregnancy can generate epigenetic disturbances and increase the rate of diseases in the offspring and their descendants to be. This phenomenon is called transgenerational epigenetic inheritance (TEI). The initial description of cases of TEI was done through experiments studying reproductive dysfunction (particularly in males) after exposure to environmental toxicants, categorized as endocrine disrupting chemicals (EDCs); these are exogenous chemical compounds that can interact with endogenous hormone receptors and cause hormone-like responses in the affected organism.

Initial Evidence for Transgenerational Effects Induced by the Environment

The first evidence in animal models indicating that gestational exposure to EDCs could generate disease phenotypes capable of being transmitted to future generations was obtained in a study testing for the reproductive effects of Diethylstilbestrol (DES). DES is an estrogenic compound originally prescribed to women to prevent miscarriages and other reproductive complications, in use from the 1930 to the 1970s. Later observations revealed that DES administration was associated with reproductive defects in the offspring of the treated women. While studying reproductive effects of a gestational exposure to DES in rodents, researchers reported in the year 2000 that administration of DES to pregnant rats during early post-implantation development generated reproductive abnormalities in the following generations (Newbold et al., 2000). These abnormalities in the male offspring of the F1 and F2 generation included increased susceptibility for proliferative lesions in the *rete testis*, which are usually of rare incidence, as well as increased tumors formed in other areas of the reproductive tract (Newbold et al., 2000). Based on these results, the authors suggested that epigenetic alterations could be involved in the generation of these reproductive abnormalities, and their transmission to future generations. In the year 2005, while reproductive effects of the fungicide vinclozolin were being studied, came the first description of an environmentally-induced transgenerational inheritance process confirmed to be related to epigenetic changes in the germ line (Anway et al., 2005). Vinclozolin is a fungicide with anti-androgenic effects (widely used in crops around the world) that was previously shown to generate increased apoptosis in spermatogenic cells of male rodents after their mothers were treated with the compound during gestation (Uzumcu et al., 2004). Follow-up experiments demonstrated that this vinclozolin-induced increased apoptosis in spermatogenic cells was also observed in the next three generations, in absence of any further exposure of the affected offspring (Anway et al., 2005, 2006a,b).

Current Evidence for Reproductive Transgenerational Effects Induced by the Environment in Males

In addition to increased events of programmed death (apoptosis) during spermatogenesis, other male reproductive abnormalities are shown to be transmitted through TEI (Fig. 1). Moreover, a variety of environmental toxicants can trigger this phenomenon. These transgenerationally transmitted altered phenotypes in males include: kidney abnormalities (after ancestral exposures to

Fig. 1 Transgenerational epigenetic effect up to the male germinal line of the third generation of environmentally-exposed mice. Such effects “travel” throughout generations, displaying changes on the offspring directly related to the original parental exposure (F0), but also affecting the germline of the F1, which –via its semen– would pass the transgenerational epigenetic inheritance phenomenon to an F3-generation individual. Figure modified from Nilsson, E., Skinner, M.K. (2015). Environmentally Induced Epigenetic Transgenerational Inheritance of Disease Susceptibility. *Translational Research* 165(1), 12–17, <https://doi.org/10.1016/j.trsl.2014.02.003>.

vinclozolin (Anway et al., 2006a), dioxin (Manikkam et al., 2012b), DDT (Skinner et al., 2013b), and methoxychlor (Manikkam et al., 2014)), prostate abnormalities (after ancestral exposure to vinclozolin (Anway et al., 2006a)), pubertal abnormalities (after ancestral exposures to dioxin (Manikkam et al., 2012b)), and testis abnormalities (after ancestral exposures to a mixture of the pesticides Permethrin and DEET (Manikkam et al., 2012c), and to DDT (Skinner et al., 2013b)). Ancestral exposure to pharmacological levels of all of these compounds induced sperm epimutations (i.e., DNA methylation changes) in the unexposed F3 generation, therefore opening the conceptual possibility that sperm epimutations can be indicators of both ancestral exposure and susceptibility to disease (Manikkam et al., 2012a; Skinner et al., 2013b; Guerrero-Bosagna et al., 2010). Independent studies have reported TEI in response to a variety of EDCs. For example, in males, early developmental exposure to di-(2-ethylhexyl) phthalate induces transgenerationally transmitted disruption of testicular germ cell associations, reduced sperm count and decreased sperm motility in mice (Doyle et al., 2013). Also, early developmental exposure to DDE is reported to increase testicular germ line apoptosis from the F1 to the F3 generations in rats (Song et al., 2014). Interestingly, increased rate of infertility and incidence of small testes were observed in this study in the F3 but not in the F1 or F2 generations (Song et al., 2014). A summary of the current evidence reporting EDC-related TEI is shown in Table 1.

Reprogramming and Epigenetics

The transgenerational transmission of disease phenotypes is attributed to disturbances in DNA methylation that occur during the migration of primordial germ cells (at initial stages of sex determination) (Skinner et al., 2013a). This ultimately affects the epigenome of the mature sperm, which is then maintained altered in the following generations, thereby affecting the adult phenotype of the descendants. A particular aspect of this developmental period is that it is one of the developmental windows during which a so-called “epigenetic reprogramming” can occur.

Reproduction in vertebrates depends on two critical participants: the gametes (the maternal egg and the paternal sperm) and the zygote resulting from fertilization. In the latter, a most relevant event occurs under the generic name of *Reprogramming* (Fig. 2) of both the maternal and paternal genome (Hill et al., 2014). This allows the zygote to develop full potency (totipotency) to generate all the cell types present in the new embryo, as well as the extraembryonic tissues (including placenta). The primary epigenetic factors (also called marks) that determine potency are DNA methylation, histone modifications and the action of non-coding RNA (ncRNA) (Piferrer, 2013). During this reprogramming, epigenetic “marks” are removed from the DNA of the egg and the sperm, thereby restoring their cell potency immediately before the zygote is formed. This demethylation process occurs either by active or passive mechanisms (Hackett et al., 2012). Later in development, another reprogramming will occur during the formation of the primordial germ cells (PGCs) which will develop into the gametes of the offspring, depending on its chromosomal sex. The phenomenon of PGC reprogramming is basically the same as previously described for the zygote: the genome is to be stripped of essentially all heterochromatic factors/marks that could restrict developmental capacity. Imprinted genes, transposable elements (TE's) as retrotransposons (RTs), and centromeric heterochromatin, which together compose almost 50% of the genome (Lander et al., 2001) are, however, excepted from this stripping during the reprogramming that occurs during the early embryonic cleavage stage (Morgan et al., 2005). The second wave of reprogramming that occurs in the embryonic PGCs is absolutely necessary to re-establish fetal-specific imprinting, to regain the epigenetic potential required for fertilization, and for the development of the next generation individuals. In this way, some loci do not undergo demethylation, and thus become the carriers of transgenerational epigenetic memory (Lane et al., 2003).

Transposable Elements and Embryo Vulnerability

As mentioned above, demethylation of DNA in either gametes or embryos is a critical component of reprogramming. Yet it opens for the most vulnerable period owing to the risk of the expression or even the expansion of integrated ancestral viral elements within the genome (retroviruses, transposons) and are normally kept “silenced” by DNA methylation (Guo et al., 2014). Demethylation during reprogramming can cause mobilization of TEs (either retrotransposons or DNA-transposons, Wicker et al., 2007) with deleterious effects ranging from genetic instability (causing genome mutations) to cell death, genetic diseases, cancer and even infertility (Maksakova et al., 2006). However, considering that TEs are a significant part of the genome, their role might also be determinant for evolution driving, and TE's should not necessarily be related to negative effects (Chuong et al., 2017). In any case, there seems to be a liaison between environmental pressure and TEs-mediated genetic changes, particularly in relation to stress and immune responses (Van De Lagemaat et al., 2003).

Environmental Insults and Non-Coding Small RNAs

Emerging evidence suggests that miRNAs play an important role in male fertility. MicroRNAs (miRNA) are single-strand RNAs of 21–23 nucleotides, transcribed from DNA but not translated into proteins (thus generically named non-coding RNAs, ncRNAs). Important roles for these ncRNAs have been ascribed in different molecular pathways, both at transcriptional and post-transcriptional level. miRNAs undergo a maturation process from primary miRNA to a precursor of miRNA, in which the enzyme

TCDD	Rat	Oral gavage	Gestational from E8-E14	F1 and F3 generation, liver	Bisulfite sequencing	Imprinted gene Igf2, and altered DNMTs expression	Yes	M: liver abnormalities	Ma et al. (2015)
DDE	Rat	Oral gavage	Gestational from E8-E15	F1, F2, and F3 generations, sperm	Bisulfite sequencing	Imprinted DMR at the Igf2/H19 cluster	Yes	M: testis abnormalities, spermatogenic cell apoptosis	Song et al. (2014)

Fig. 2 Epigenetic reprogramming. Levels of DNA methylation from fertilization to sexual maturity. Reprogramming waves mainly occur during fertilization and gametogenesis of the new conceptus, and are necessary for the correct transmission of the epigenetics patterns through generations. Subtle changes, for example, produced by environmental toxicants, could induce epigenetically heritable changes in the offspring which, albeit not coded genetically, are made permanent in future generations. Male gametes are represented in blue line and female in pink. PGC: primordial germinal cell. Figure modified from <http://www.hannonlab.org/epigenetics>.

Drosha plays a fundamental role. The final step in the development of these molecules is carried out in the cytoplasm by Dicer and loaded onto the Argonaute protein to result in a RNA-silencing complex (RISC). This final complex is able either to restrain, or increase translation.

It is also becoming increasingly evident that non-coding RNAs in testicular somatic or germ cells play a fundamental role in spermatogenesis. Small non-coding RNAs involved in sperm production include micro RNAs (miRNAs), endogenous small interfering RNAs (endo-siRNAs), and PIWI-interacting RNAs (piRNAs). These small RNAs are categorized depending on the involvement of the RNase III endonuclease DICER in their biogenesis mechanisms. DICER is essential for microRNA processing during the haploid differentiation of germ cells. Endo-siRNAs and miRNAs are DICER-dependent, while piRNAs are DICER-independent but predominantly expressed in tissues involved in male germ line development (Yadav and Kotaja, 2014). The miRNA knockout of *Dicer* in Sertoli cells leads to testicular dysgenesis and infertility due to the disruption of Sertoli cell architecture (Papaioannou et al., 2009). The identification of the roles of particular miRNAs during spermatogenesis should lead to the use of miRNAs as predictive or diagnostic indicators.

In addition to DNA methylation, miRNAs are starting to emerge as important players in the process of TEI. Particularly, a specific type of small RNAs named sperm transfer RNA-derived smallRNAs (tsRNAs), could be implicated as paternal epigenetic factor that may mediate the inheritance of diet-induced metabolic disorders. For example, injection of sperm tsRNA fractions from males consuming a high fat diet into normal zygotes has generated metabolic disorders in the F1 offspring, together with altered gene expression of metabolic pathways in early embryos and pancreatic islets of F1 offspring (Chen et al., 2016). Interestingly, this sperm tsRNA-mediated inheritance is unrelated to DNA methylation at CpG-rich regions. Moreover, while these tsRNAs are found at minimal levels in testicular spermatozoa, their amount increases substantially through their maturation within the epididymis. Therefore, the presence of tsRNAs in mature spermatozoa does not merely result from degradation of tsRNAs present during spermatogenesis (Sharma et al., 2016). In this sense epididymosomes, exosomal vesicles from the epididymis epithelium, are able to fuse with the luminal spermatozoa and most likely load these RNAs along the sperm maturation process. Overall, recent evidence points towards (i) the paternal diet being able to influence the phenotype of the offspring via the inclusion of varying amounts of specific small RNAs in spermatozoa (including tRNA fragments) throughout the male reproductive tract, and (ii) that these tRNA fragments in mature sperm can regulate expression of transcripts, driven by endogenous retro-transposable elements (Sharma et al., 2016).

TE-expression during reprogramming seems to act via the so-called PIWI (P-element Induced Wimpy testes) pathway. This is a small RNA-based pathway of a post-transcriptionally regulatory system of RNA interference, built by PIWI proteins (belonging to the Argonaute family) and associated PIWI-interacting RNAs (piRNAs), all functionally acting in a similar fashion as the miRNAs described above, being key controllers of retrotransposon expression (Vagin et al., 2006).

Germline Development: Is it Here Where Transgenerational Somatic Epigenetic Effects Are Caused?

The development of the germ line plays a crucial role in the phenomenon of TEI. DNA methylation and expression patterns are disrupted in PGCs when the maternal exposure to vinclozolin occurs between the onset of gonadal sex determination and after testis cord formation (Skinner et al., 2013a,b). These alterations are maintained in subsequent generations (Skinner et al., 2013a,b; Anway et al., 2008) and will, in theory, influence the epigenome of the mature spermatozoa.

However, despite what is known today and of an increasing number of studies focusing on the mechanisms behind TEI, there are still gaps in knowledge regarding the exact biological pathways by which environmental insults interfere with germ line epigenetic

THE 'EPIGENETIC DOMINO' EFFECT

Fig. 3 Schematic representation of an “Epigenetic Domino” effect in which environmentally-induced germ line epigenome modifications will generate subsequent amplified epigenomic and transcriptomic effects in somatic cells. Figure modified from Guerrero-Bosagna, C., Skinner, M.K. (2014). Environmentally induced epigenetic transgenerational inheritance of male infertility. *Current Opinion in Genetics & Development* **26**, 79–88, <https://doi.org/10.1016/j.gde.2014.06.005>.

reprogramming and subsequently, with the phenotype of individuals in future generations. Experiments have been performed to determine whether somatic gene expression and epigenetic patterns are transgenerationally altered in somatic tissues in close contact with gonadal development (Guerrero-Bosagna et al., 2013; Nilsson et al., 2012). Studies in Sertoli (Guerrero-Bosagna et al., 2013) and granulosa (Nilsson et al., 2012) cells have shown altered epigenomes and transcriptomes in the F3-generation after an ancestral exposure to vinclozolin. In Sertoli cells, vinclozolin-induced transgenerational DNA methylation changes were observed with distinct degree of connections to gene expression changes in the same cells (Guerrero-Bosagna et al., 2013). These connections included genomic proximity as well as functional correlations. Importantly, changes in gene expression do not necessarily correlate to changes in DNA methylation. This is due, in part, to the fact that changes in DNA methylation in somatic cell types developmentally precede and influence later changes in gene expression in the same tissues. Similarly, DNA methylation changes in the germ line will influence somatic DNA methylation patterns later on in the individuals that will be originated out of these germ cells; however, the genes affected in each case will not necessarily be the same. This corresponds to an “epigenetic domino” process in which the germ line epigenome will influence the epigenome somatic cells in the originating individual, hence, ultimately affecting gene expression. During this process, an amplification effect is observed, in which few altered genes in the germ line can produce an increased number of somatic epigenetic alterations, which will in turn generate an even larger number of genes altered in terms of expression (Fig. 3).

Concluding Remarks

There is increasing evidence that parental exposures to environmental insults affect male reproduction, both in exposed individuals and in coming generations. These alterations are mostly due to changes in the epigenome of somatic and germ cells. In the scenario when the germ line epigenome is affected by environmental exposures, then epigenetic alterations can be transmitted to future

generations, in a process known as TEI. Although this phenomenon have only started to be described in detail at the first decade of this century, evidence is rapidly accumulating not only in reproduction but also in many other biological aspects. Considering the relevance of the fact that certain environmental exposures can trigger diseases that last for generations, more is needed to be know about which specific compounds are able to trigger a process of TEI, at which amounts, in which developmental stages, and what are the effects of combined exposures (of multiple compounds). These gaps in knowledge, together with the relevance of this biological process to human and animal health, warrant an expanding interest by the scientific community in performing research in the many aspects related to TEI.

Glossary

Aneuploidy Aneuploidy is presence of abnormal number of chromosome in cell.

Azoospermic men Men whose sperm contains no spermatozoa.

Cryptorchidism It is a congenital anomaly of male sexual development where undescended testis are absent of the scrotum and stay in abdominal cavity.

DNA methyltransferase DNA methyltransferase is an enzyme involve in the transfer of methyl group on DNA sequence.

Epigenetic Epigenetic is a study of changes in gene expression without affecting DNA sequence.

Hypospadia Hypospadia is a congenital anomaly where urethra opening is not at the head of the penis but on its ventral side resulting to an incomplete closure of the urethral folds.

Methylation It is an addition of a methyl group on a substrate.

miRNAs Small RNA segments able to bind messenger RNA and to suppress gene expression.

Oligozoospermic men Men with a quantity of spermatozoa in sperm lower than normal (< 20 million of spermatozoa per milliliter).

Paternally imprinted loci Position on the chromosome marked with information about its parental origin, here the father.

Secondary sex ratio It is defined as the ratio of male-to-female live births. The first sex ratio is the ratio of male-to-female conceptions.

Telomere Telomere is tandemly repeated hexameric sequence of nucleotides whose role is to preserve the stability of the genome.

X-chromosome inactivation Randomly inactivation of one X chromosome in mammal's females (XX) during development to have the same content of X-located genes than in males (XY).

Introduction

Environmental factors can disrupt early developmental process during pregnancy and early childhood, which constitute critical windows of vulnerability and lead to diseases or dysfunctions development after birth until adulthood. This concept corresponds to the Developmental Origins of Health and Disease (DOHaD) which was first given by David Barker in the 1980s. Now, other evidences have shown that environmental stressors can affect female and male gametes before conception and may transfer effects to the future individual through different mechanisms.

In this article, we will see first how preconception exposure of male to physical, chemical and socio-cultural agents will be able to affect offspring (Fig. 1) and then, we will do an overview of the main epigenetic mechanisms possibly involved in paternal inheritance.

Impact of Male Preconception Period on Human Reproduction

Physical Agents

We will focus here on the preconceptional effect of two physical agents, the temperature and the radiations.

Temperature

In Human, spermatogenesis occurs between 34°C and 35°C that mean 2–3°C below the temperature of the body. Many studies have shown that an increase of 1°C to 1.5°C of the scrotal temperature can induce a decrease of testis size, a disruption of sperm production and can affect sperm morphology. In the case of cryptorchidism, a congenital malformation where testis fails to descend from the peritoneal cavity to the scrotum, spermatogenesis does not occur due to a high temperature (Mieusset et al., 1995). The potential use of testicular heating for contraceptive purposes has been investigate the first time in 1921 by Martha Voegli, a Swiss physician. The method was for men to take a bath at 46–47°C during 45 min every day during 3 weeks. She reported this technique was efficient and induces no malformation in babies after recovery of fertility. One study performed in sauna-exposed Finnish men demonstrated that two sauna sessions per week for 3 months during 15 min induces a significant, but reversible, impairment of spermatogenesis (Garolla et al., 2013). Use of laptop on the lap induce also an increase of genital area temperature in men witch can represent a risk for normal spermatogenesis process. A reduction of fertility relative to occupational heat stress has also been

Fig. 1 Male preconception exposition affects development and health of the offspring. Environmental factors as physical, chemical and socio-cultural agents affect male gametes. Spermatozoa are responsible to the transmission of information to the next generation leading to an alteration of development, a modification of the sex ratio, a decrease of the success of assisted reproductive technologies (ART) and an increase of the risk of diseases.

observed. It is the case for welders or men working in ceramic industry exposed to high temperature whose have an alteration of spermatogenesis process leading to an increase of infertility incidence.

Radiations

Radiations are another physical agents affecting reproduction in male. It corresponds to energy coming from a source and traveling through space and some material as Human body. Human can be exposed to two types of radiation: non-ionizing radiations via phone, computer, radio and so on or ionizing radiations via medical X-rays or radioactive source.

A meta-analysis performed in 2016 by Ryan C. Lewis and collaborators report that exposure to power-frequency magnetic fields (50 or 60 Hz), some non-ionizing radiations, may be link to infertility and adverse pregnancy outcomes etiology (Lewis et al., 2016). For example, exposition to magnetic field ≥ 1.6 mG increases the risk of poor semen quality and the risk increases with exposure duration in a dose-dependent manner. In vitro experiment show that radiofrequency electromagnetic waves (870 MHz) from cellular phone may lead to oxidative stress in semen samples and a decrease of sperm mobility and viability. Electromagnetic waves coming from laptop computers decrease spermatozoa motility and increase DNA fragmentation.

Ionizing radiation is a classical mutagen witch can increase chromosomal aberration, the frequencies of chromatin exchange and DNA double-strand breaks. Claudius Regaud shown in 1977 that radon, a chemical element witch produce ionizing radiation, induces spermatogonia cell death and ram sterilization (Regaud, 1977). Populations occupationally exposed to ionizing radiation have less good sperm parameters with an increase of sperm DNA fragmentation. A strong association was done between preconception radiation exposure of father and development of leukemia in offspring living near Sellafield nuclear plant in united Kingdom (Gardner et al., 1990). Other studies about workers exposed to ionizing radiation failed to confirm these finding. In fact, any correlation was done between exposition and an increase of adult-onset multifactorial diseases among offspring of A-bomb or an increase of cancer in offspring of surviving cancer patients receiving an high dose of mutagen by radio- and chemotherapy.

Chemical Agents

Human are exposed every day to chemical agents produce by human activity. More than 100,000 substances are present around us and can impact our health and health of our children. In this section, we will focus only on some categories of substances, the drugs, the phytosanitary products and some plasticizers for which scientific community accumulate significant data.

Drugs

Chemotherapy induces gonadal dysfunction due to a toxic effect on spermatogonia stem cell. The differentiated germ cell and the Leydig cell seem to be more resistant to treatment. Patients who received chemotherapy treatment may become oligospermic or azoospermic but our secondary sexual characteristics are conserved as testosterone production by Leydig cell is in principle not affected. The effect on testicular function is really specific of the drug and doses used during treatment. For example, children who received chemotherapy treatment for Hodgkin's lymphoma presented an important alteration on seminiferous epithelium up to 10 years after treatment. Abdomino-pelvic or testicular radiotherapy can affect reproductive function. At the median testicular radiation dose (0.1 Gy), any reduction of sperm count is observed 1 year after treatment. In some cases, irradiation of testis at a high dose (20 Gy) leads to permanent azoospermia. Chemotherapy has the potential to induce germ cell mutation which can lead to

genetic disease in the next generation. For the moment, there is not clear evidence in the literature of a relationship between chemotherapy treatment in male survivors of cancer and genetic disease in children. As the risk of sperm aneuploidy decreases over the time, contraception is recommended for 1 year after the end of the treatment.

Other drugs can impact male spermatogenesis. If the treatment cannot be stop or if the effect is potentially irreversible, the cryopreservation of sperm patient must be proposed. It is the case for some immunosuppressant as Azathioprine and Mycophenolate mofetil. These compounds are mutagenic and teratogen when taken by pregnant women but no significant increase of preterm birth and malformation have been observed in children born of treated-father. Some drugs affect sperm parameters in a reversible manner. It is the case for hormonal treatment using anabolic steroids or testosterone, for antiandrogenic drugs as cyproterone acetate, for opiates, and for some nonsteroidal anti-inflammatory drug (NSAID) and salicylates. Tramadol, an analgesic, and some antidepressant therapy as sartans can also affect sexual function (Semet et al., 2017).

Phytosanitary products

Human is exposed every day to a large scale of chemical compounds affecting male fertility alone or in association. The population of greenhouse workers or farmer is importantly exposed to phytosanitary products. Some studies showed that male exposure to pesticides induces a decrease of fecundability and a prolonged time-to-pregnancy while others did not. It is very difficult to establish the causal link between pesticide exposure and endocrine disruptors found in environment and male congenital malformations. Despite this, some epidemiological studies correlated parental occupations in agriculture work and a higher prevalence of cryptorchidism, and a moderate association with hypospadias in son (Fernandez et al., 2007). Some studies associate an increase of the risk with mother exposure during gestation, other one with father exposure during preconception period. Preconceptional maternal and paternal presence of several persistent organic pollutants (POPs) in serum was associated with variation of birth weight offspring (Robledo et al., 2015). These compounds can be found in industrial chemicals or pesticides.

Another indicator of reproductive problem can be a modification of the sex ratio. Generally 105 males are born for 100 females. Men exposition to dioxin, a POP found among other in few pesticides, after explosion at a chemical plant in Seveso (Italy, 1976) or to the gonadotoxic nematocide DBCP (1,2-dibromo-3-chloropropane), induce a reduction of sex ratio compared with children born before paternal exposure.

During the last decades, several studies highlighted the relationship between paternal occupational exposure and the risk factors for some childhood cancers. There are now strong evidences between childhood leukemia, childhood nervous system tumor and paternal exposure to pesticides. With these case-report studies, it can be hypothesized than exposition to chemical product can cause alteration in sperm DNA of father before conception and then affect cancer risk in their children. We cannot exclude here the possibility that father can bring some mutagen pollutants into home where embryo and/or fetus is exposed via the mother.

Plasticizers: The cases of Bisphenol A and phthalates

Plastics are widely used and present everywhere around us. This induces the production of a very high quantity of plasticizers as Bisphenol A (BPA) and Phthalates found in a variety of commercial products as plastics bottles and epoxy resins for BPA and food packaging and cosmetics for phthalates. BPA and phthalates are known to be endocrine disrupting chemicals. Some epidemiological studies have shown that exposure to phthalates or BPA during pregnancy are associated with a decrease of anogenital distance in newborn boys, an indicator of an antiandrogenic exposure. Recently, Smarr and collaborators designed a population-based prospective cohort in United States to explore the effects of environmental factors on critical windows of reproduction and development. They examined the association between parental urinary presence of BPA and 14 phthalates metabolites and birth size in a cohort of 233 to 237 children from 501 enrolled couples. Authors suggest that "preconception maternal and paternal urinary concentration of BPA and specific phthalates metabolites may be associated with smaller birth size and increased gestational age", but this correlation is parent and chemical specific and that paternal preconception exposure to BPA and phthalates were associated with female excess, that mean a decrease of the secondary sex ratio (Smarr et al., 2015). Contrarily, maternal preconception exposure to these compounds were significantly associated with a male excess. In the same cohort the authors shown that father preconception urinary concentrations of phthalates metabolites were associated with an increase of the time-to-pregnancy (Buck Louis et al., 2014).

In couples undergoing an assisted technology treatment (ART), the presence of phthalates metabolites in the urine of father can be associated with a decrease of blastocyst quality (Wu et al., 2017) implantation odds and live birth (Dodge et al., 2015). Urinary concentrations in mother of a known metabolite of phthalates, the di(2-ethylhexyl)phthalate (DEHP), were associated with a reduction of the probability of life birth and of oocyte yield (Hauser et al., 2016) in women undergoing ART or with pregnancy loss in women without known problem of reproduction (Toft et al., 2012).

Preconceptional and gestational exposition to plasticizers can affects reproduction and birth outcome but can also have long term effects which are easier to highlight in animal models. Studies performed in rodent demonstrate that preconception exposure to BPA in adult male rats can transmit spatial memory deficits to male and female offspring (Fan et al., 2013) and that gestational exposure to BPA alters social behavior in juvenile female's mice (Wolstenholme et al., 2011). In this last one, authors shown that BPA induced change in the expression of two methyltransferases genes (Dnmt3a and Dnmt1) coding for enzyme involved for DNA methylation. We can suppose here than change in DNA sequence methylation status can be responsible of the behavior effect of BPA.

Sociocultural Agents

We saw above that physical and chemical agents have a preconceptional impact. We will see here that reproductive function can also be affected by sociocultural agents as stress, age, the consumption of tobacco and alcohol and the nutrition.

Stress

A rich literature focuses on the effect on maternal stress on offspring development but very little things are known about the preconception paternal stress effect. Harker et al. demonstrate in rat that preconception paternal stress can have an effect on the neurodevelopment and behavior of male and female offspring (Harker et al., 2015). This change in behavior can be linked to change in methylation in prefrontal cortex (Mychasiuk et al., 2013). In mice, maternal separation of the offspring during postnatal development induces altered anxiety and depressive-like behaviors that persist across generation. In these maternally-separated males, there is a modification of the status of DNA methylation in some genes in sperm (Franklin et al., 2010).

Natural disaster or war can constitute a stress for population. For example, some authors reported a reduction in sperm motility just after the Kobe earthquake and then, a decline in the secondary sex ratio (Fukuda et al., 1996, 1998). A decrease of sex ratio also been observed after September 11 attack in New York, economic downturns and war which can be due to an alteration in semen quality or spontaneous abortion. A population-based prospective cohort study confirmed these data and associates the presence of preconception salivary cortisol, a physiological indicator of stress, with a decrease of odds of male birth (Chason et al., 2012).

Age

Over the last decade, the average of paternal age significantly increases due to an increase of life expectancy, the use of contraception methods or change in various socioeconomic factors. Studies have demonstrated that the increase of paternal age affects testicular function, reproductive hormone production and sperm parameters (for review, Sharma et al., 2015). The increase of paternal age can also be associated with sperm DNA fragmentation (Johnson et al., 2015) affecting the success rate of ART, the level of miscarriages, as well as the early embryonic development (for review, Sharma et al., 2015). However it has also been reported that telomere length in sperm increases with paternal age and that there is a positive correlation between paternal age and sperm telomere length in offspring. For now, the role of telomere length in spermatogenesis and fertility is unclear but length of telomere is significantly shorter in oligozoospermic men compared to normozoospermic one (Ferlin et al., 2013). Increase of paternal age can also be responsible for the increase of error in DNA sequence of germline leading to the accumulation of de novo mutations in spermatozoa. A study performed on the entire genome of Icelandic parent-offspring estimate an increase of two mutations per year of father's age (Kong et al., 2012). The increase in de novo mutation rate is the major source of paternal age affect disorders. In fact, advanced paternal age has been associated to neuro-cognitive disorders as schizophrenia and autism, autosomal dominant disorders as retinoblastoma, congenital abnormalities as cleft lips and so on in offspring (for review, Sharma et al., 2015). The epigenetics pattern of sperm is also modified with age as the global level of 5-methyl-cytosine increase by 1.76% per year (Jenkins et al., 2013). Age can also induce chromosomal aneuploidy. Only 1% of aneuploidy pregnancy leads to live birth with high number of congenital malformation and/or mental retardation.

Tobacco

A meta-analysis of 20 studies with 5865 males participants over 13 years-old conducted by Sharma and colleagues concluded that cigarette smoking has a negative effect on sperm parameters (Sharma et al., 2016). It has been shown that fathers smoking affect the time-to-pregnancy and then couples fertility. This risk increase with the number of cigarette smoked per day and the smoking duration. Paternal smoking can also affect health of the offspring through damage to the genome and epigenome of sperm. For example, studies performed in China, Colombia or US highlight that the risk of childhood acute leukemia significantly increases with paternal preconception smoking.

Alcohol

Alcohol is known to impair fertility and to be teratogen. Alcohol consumption by women during pregnancy lead to abnormal fetal development resulting in fetal alcohol spectrum disorders (FASDs). FASDs were first attributable to maternal alcohol consumption but some studies suggest that preconception paternal alcohol consumption may contribute to FASDs development. Some epidemiological data associated preconceptional paternal alcohol consumption and a lowered birth weight, hyperactivity and lowered cognitive abilities in offspring. Alcohol has been shown to lower the level of DNA methyltransferase transcription in some organs such as testis. It has been shown that chronic alcohol consumption can be correlated with demethylation of paternally imprinted loci in sperm DNA. This effect could result in epigenetic modification on sperm DNA and an alteration of gene expression required for normal embryonic development leading to offspring with FASDs symptoms (Ouko et al., 2009).

Nutrition

In human, the impact of maternal nutrition on offspring development and risk disease was fully described in the literature. More recently, research has shown that paternal diet can affect future generations. In men, an increase of the body mass index is associated to a decrease of sperm mobility, an increase of sperm abnormality and sperm DNA fragmentation and a reduction of pregnancy rates. Paternal obesity is also associated with a decrease of blastocyst development and live birth rate following ART. It has been shown that low amount of dietary recourses during preadolescent period of fathers or grandfathers was correlated with a decrease

of cardiovascular or diabetes mortality of children. As this phenotype appears very quickly, it could not be the consequences of DNA mutation but probably due to modification to epigenetics status of some genes. Heijmans and collaborators shown than men and women prenatally exposed to famine during the Dutch Hunger during the winter 1944–45 of the II world war have, 6 decades later, a decrease of the level of DNA methylation of the imprinted insulin-like growth factor II (IGF2 gene) (Heijmans et al., 2008). This gene is a key factor in human growth and development and his hypomethylated status can be associated with increased likelihood of obesity (Soubry et al., 2013). The effect of father diet on the next generation was verified in rodent models. In rat, an high-fat diet in adulthood induce appearance of impaired pancreatic function in female offspring which is correlated with an alteration of DNA methylation of genes involved in insulin or glucose metabolism or expressed in pancreatic tissue. In male mice, a low-protein diet affects the status of DNA methylation of genes or the expression of some microRNAs in hepatic tissue.

Some studies have shown that preconceptional mother diet affects sex ratio. In Human, male fetus appears to need a higher caloric demand. For example, malnourished African woman produced more daughters than sons. In Ethiopia, a positive correlation between the percentage of male birth and a better nutritional state was observed. A study performed on a cohort of 740 nulliparous British women who were unaware of their fetus's gender, demonstrated than the sex of the fetus is associated with diet of the mother at conception. Fifty six per cent of women with the highest energy intake give boys, against 45% with a lowest energy diet (Mathews et al., 2008). These data support the hypothesis that mother had a better chance to give male if the nutriment intake was higher prior conception.

The preconceptional diet of the father affects, as for the mother, the disease risk in descendants. This paternal transmission can be inherited via the modification of epigenetic status of genes involved in development or in the regulation of physiological process.

Overview of Epigenetic Mechanisms Possibly Involved in Paternal Inheritance

Epigenetics changes in sperm have been proposed as one of the possible mechanism through which paternal gamete can impact offspring. Epigenetic changes affect gene expression without modification of DNA sequence. This epigenetic inheritance is mediated by epigenetic modifications as DNA methylation, posttranslational modifications of histone or small noncoding RNAs in male germline and is transmitted to the next generations where metabolism, behavior, neurodevelopment or reproduction capacity can be affected (Fig. 2).

DNA Methylation

DNA methylation corresponds to an addition of a methyl group (CH_3) on DNA sequence on cytosine on cytosine/guanine (C/G) dinucleotides. The most widely characterized type of methylation is the addition of a methyl group on the carbon number 5 of the cytosine giving rise to 5-methylcytosine (5-mC). DNA methyltransferases (DNMTs) are enzymes required for the establishment but also the maintenances of DNA methylation patterns. Other enzymes are required to remove methylation group as enzymes of TETs family. This process is essential for normal development, cell differentiation and involved in key process as parental imprinting and X-chromosome inactivation. As CpG islands are present in promoter regions, DNA methylation acts in this case as repressor of transcription. DNA methylation patterns are largely erased, soon after fertilization, to remove paternal mark and then reestablished in Human when fetal gonocyte give rise to prespermatogonia. This remethylation process continues in male germ cell until spermatocyte stage just before the beginning of meiosis.

An alteration of DNA methylation can be an explanation of the preconceptional impact of environmental factors on offspring. It has been shown in literature than some compounds as BPA and phthalates can affect DNA methylation. As mention before, other factors as stress, nutrition or alcohol consumption can affect this epigenetic process and then lead to an alteration of gene expression involved in development and disease.

Histone Modifications

Histones are proteins linked to DNA which participate to special organization of chromatin. Posttranslational modifications of histones by acetylation, methylation, ubiquitination or phosphorylation induce change of chromatin organization affecting inactivation/activation of gene transcription.

In sperm, histones are exchange by protamines in spermatocyte to allow a better compaction of DNA. In Human, approximately 15% of histones are retained in chromatin of spermatozoa predominantly in some regions of genome important for early development of embryo. Anomalies in histone–protamine transition or histone retention have been detected in patient with problem of fertility.

It can be possible that some environmental factors can altered the level of histone in sperm or modify histone marks and in this way affect the next generation. In China, a case-control study performed on semen samples from 147 heavy smokers and 175 nonsmokers receiving infertility treatment highlight that smoking and abnormal spermatogenesis are associated with anomalies in histone-to-protamine transition (Yu et al., 2014). Atrazine, a widely-used pesticide in United States banned in Europe in 2003, have been shown to interfere with the level of histone methylation and to induce a transgenerational decrease of protamine level in mouse sperm (Hao et al., 2016). Other compound as diethylstilbestrol (DES), an antiabortive medication used by woman

Fig. 2 Overview of epigenetic modification possibly involved in transmission of paternal preconceptional information. The modification of spermatozoa DNA content by epigenetic process induced by some factors can activate (ON) or silence (OFF) genes involved in development and disease. These include (1) the DNA methylation: the methylation of DNA leads to repression of gene transcription (2) the modification of histone where acetyl or methyl groups are added. Histone acetylation leads to opening of DNA molecule and gene activation. The effect of methylation on gene activation/repression is more complex and depends of the localization of methylation site and (3) the noncoding RNAs can bind messenger RNAs (mRNA) and induce their degradation.

until 1971, interferes with histone methylation. DES was associated to an increased risk of hypospadias, a congenital anomaly, in males exposed during development which can persist until the third generation (for review, [Bouty et al., 2015](#)).

Noncoding RNAs

Noncoding RNAs (ncRNAs) are functional RNA molecules coming from DNA molecules but not translated into proteins. ncRNAs are divided into two groups, the long ncRNAs (≥ 200 nucleotides) and the small ncRNAs (≤ 30 nucleotides). The small ncRNAs are composed of three major classes: the microRNAs (miRNAs), the short interfering RNAs (siRNAs) and the piwi-interacting RNAs (piRNAs). ncRNAs can act transcriptionally and posttranscriptionally on the control of gene expression.

Experiments performed in knockout mouse have revealed that small RNAs are key actors of spermatogenesis. In Human, down-regulation of miRNAs was observed in spermatozoa of subfertility patients compared to control men ([Abu-Halima et al., 2014](#)) and miRNAs clusters are over-expressed in malignant germ cell testis cancer (TGCC) ([Novotny et al., 2012](#)). The proof was done in literature that modification of the pattern of ncRNAs in sperm can be the mirror of paternal exposition to environmental factors and can modify behavior and offspring physiology.

A Swiss team published in 2014 a paper in *Nature Neuroscience* on the impact of sperm small ncRNAs transmission of early life traumatic sperm across generation ([Gapp et al., 2014](#)). They first demonstrated that early life exposure of mice to traumatic stress affects microRNAs expression in sperm and behavior and metabolic responses in offspring. More importantly, they injected sperm RNAs of traumatized animals into wild-type fertilized oocytes and showed a comparable effect than previously described in the next generation. These results showed a causal link between an alteration of sperm RNA in father due to an early life stress and an effect on behavior in offspring.

Pharmaceutical Drugs

Introduction

During the last century, pharmaceutical drugs have become ever more intertwined in everyday life. At the same time, infertility affects approximately 10%–15% of the population in developed countries, with about half of the cases recognized as being caused by male infertility. Genetic differences, fetal exposures, recreational drug or alcohol abuse, dietary issues, environmental or occupational exposure to reprotoxicological agents, and pharmaceutical drugs are all among known causes that may result in decreased fertility (Skakkebaek et al., 2016). Due to these multiple factors underlying male infertility, it is hard to estimate the number of men whose fertility is clinically obstructed by drugs. It remain, however, that drug use is high. During the period from 2009 to 2012, approximately half of the U.S. population (48.7%) had taken a prescription drug in the last 30 days, with more than 20% of the population (21.8%) having taken three or more prescription drugs during the last month (Center for Disease Control and Prevention). At the same time, an increasing number of patients are placed on long-term medication regimens at a young age (including potential mothers) due to for example, chronic migraine, epilepsy or clinical depression, resulting in a substantial number of males being at risk of experiencing a decrease in fertility due to side effects of drug treatment. The last 50 years have shown that this risk is not negligible, as drugs have been shown to disrupt male reproduction through both prenatal and adult exposures by both hormonal and non-hormonal mechanisms.

Fetal Exposure to Pharmaceutical Drugs and Reproduction

Thalidomide

The maternal use of thalidomide (alpha-phthalimido-glutarimide) and the resulting prenatal exposure resulted in a medical disaster that still resonate today more than a half a century later. The exposure included more than 10,000 children being born with a range of severe and debilitating malformations (Smithells and Newman, 1992). Thalidomide was developed and introduced in an era where formal testing for harmful effects was not undertaken. It was prescribed as a nonbarbiturate hypnotic sedative able to produce deep sleep without hangover or risk of dependency and with the important property that overdoses caused merely prolonged sleep. Importantly, it became very popular for its secondary anti-emetic effects among pregnant women suffering of morning sickness and it was widely available without prescription. In Germany, it became a top-selling sedative and an estimated 14.6 tons was sold in 1960. Among the many birth defects caused by thalidomide, the prenatal exposure resulted in large range of external and internal malformations including small or complete absent testes, mal-descended testes (cryptorchidism), and midline fusion defect of the male ventral urethra resulting in misplaced urethra opening (hypospadias; see Table 1). Evidence show that there is likely no safe time for taking the drug during pregnancy. However, the majority of damages to the forming infant, including the reproductive defects, was in a short time sensitive window extending no more the 16 days between day 20 and 36 after conception during first trimester. Reports indicate that as little as a single 50 mg tablet of thalidomide during this sensitive window is sufficient to cause birth defects in up to 50% of pregnancies. The mechanisms behind the malformations are still debated, and it is now likely that thalidomide may act in multiple tissues through different and likely tissue specific mechanisms. These mechanisms include anti-angiogenesis, induction of reactive agents, and by binding specific molecular targets, including tubulin and the androgen receptor (AR) (Smithells and Newman, 1992). The fact that thalidomide can bind as antagonist to AR and hence block pivotal androgen like testosterone during development may account for some of the milder malformations like cryptorchidism and hypospadias, while the complete absent of testis are more likely associated with the anti-angiogenesis effects. Hence, the defects observed after prenatal thalidomide exposure are likely results of both reduced or blocked hormonal actions and non-hormonal effects.

Table 1

Prenatal exposure	Timing window	Reproductive effects	Mechanisms
Thalidomide	Throughout gestation but increased sensitivity in the first trimester	Absent or malformed testes (infertility), cryptorchidism, hypospadias	Multiple mechanisms incl. anti-angiogenesis and blocking the androgen receptor
Diethylstilbestrol (DES)	First trimester	Cryptorchidism, hypospadias, transgenerational effects	Estrogenic
Mild analgesics	First and second trimester	Cryptorchidism, hypospadias, reduction in anogenital distance	Anti-androgenic

Diethylstilbestrol

A decade after the initial reports showing effects of thalidomide, prenatal exposure to a hormonal active compound, the synthetic, nonsteroidal estrogen diethylstilbestrol (DES), was shown to be associated with reproductive developmental disruption and subsequent congenital malformations (Swan, 2000; see Table 1). DES was prescribed for pregnant women from the late 1930s to the 1970s in the belief that it would prevent spontaneous abortions and premature births, resulting in >2 million pregnant women in the US using the compound between 1940s and 1960s. In the 1970s, studies published on prenatally exposed males showed increased risk of the congenital reproductive malformations cryptorchidism and hypospadias. In 2009, a study with >1000 exposed sons supported these earlier investigations, showing an increased risk of urogenital abnormalities with associations strongest for exposure occurring in early gestation. Hence, cryptorchidism was for example, significantly associated with prenatal DES exposure that began before the 11th week of gestation (Palmer et al., 2009). Moreover, DES may increase the risk of congenital malformations even in the second generation, as the sons of in prenatally exposed women have a higher prevalence of hypospadias than other males suggesting an trans-generational epigenetic effect by DES (Skakkebaek et al., 2016). Effects on sperm quality remain disputed, as some studies have reported lower sperm counts, decreased sperm motility, and abnormal sperm morphology in men exposed prenatally to DES, while other studies have reported no differences. As DES is associated with the occurrence of vaginal/cervical clear cell adenocarcinoma in DES exposed daughters, an increased risk of testicular cancer in DES sons has also for a long time been suspected without clear associations been made (Swan, 2000). Moreover, reports have suggested a possible link between behavioral and psychosexual effects of prenatal DES exposure. However, a study from 2003 of 2600 men taking part of the world's largest cohort of individuals with documented prenatal exposure to DES researchers concluded that not enough evidence was available to prove such associations. Although the effects on sperm quality, testicular cancer and sexual behavior remain to be completely elucidated, the prenatal exposure to DES, and the subsequent investigations conducted in order to understand the effects of an estrogenic compound on male development, contributed to laying the foundation for the development of the field of endocrine disruption. Through the estrogenic effects of DES it became clear that hormonal active compounds can disturb the delicate reproductive development. This realization in turn was instrumental for the development of the estrogen hypothesis in the early 1990s, proposing that prenatal exposure to multiple xenobiotic estrogens in for example, plastic and the diet from plants and milk could disrupt development, resulting in reproductive decline among men (Sharpe and Skakkebaek, 1993).

Mild Analgesics

In the recent decade, it has been suggested that xenobiotic estrogens could function in connection with anti-androgens during gestation in a cocktail effect (Skakkebaek et al., 2016). In this context, mild analgesics (hereafter called analgesics) have received increasing attention as they show anti-androgen properties (see Table 1). Comprising of NSAIDs and acetaminophen (paracetamol), analgesics are typically used to relieve pain, fever and malaise. NSAIDs are also used in connection with pre-term labor and in inflammatory diseases and chronic musculoskeletal pain and through the inhibition of auto- and paracrine active prostaglandins. The drugs have been on the market for many decades (>100 years for acetylsalicylic acid (aspirin), ~60 years for acetaminophen and ~50 years for ibuprofen) and they are now in most households in the Western world. Moreover, sales of analgesics have been steadily increasing over the past 20 years and are now the most commonly used over-the-counter drugs worldwide. Of concern is that analgesic use during pregnancy is generally high especially for acetaminophen as it is used for common symptoms without the need to consult a physician or pharmacist. This concern have increased after analgesics in two studies in 2010 suggested an association between prenatal analgesic exposure and congenital cryptorchidism (Kristensen et al., 2016). A purely epidemiological study, using hospital registry data for cryptorchidism, reported that exposure to acetaminophen for 4 weeks resulted in an increased risk (Jensen et al., 2010). The second study using a standardized assessment of cryptorchidism combined with experimental rodent approaches showed that use of analgesics during especially the second trimester increased the risk of cryptorchidism through anti-androgenic mechanisms. The study also showed that this risk remained significant when ibuprofen and acetylsalicylic acid were examined separately, and a similar tendency was seen for acetaminophen. The risk was increased if the exposure was >2 weeks with similar results obtained in separate analyses for acetaminophen and acetylsalicylic acid. The risk was highest if the exposure included more than one compound simultaneously for >2 weeks, suggesting an additive cocktail effect. The study also included a cohort from Finland in which the associations were not significant (Kristensen et al., 2011). However, subsequent studies have found similar associations to both cryptorchidism and hypospadias together with reductions in anogenital distance among infants, all supporting the notion that analgesics are anti-androgenic compounds. As the same time, it has become clear that from urinary analysis for acetaminophen that people in Western world are ubiquitously exposed to this drug (Kristensen et al., 2016). In addition to intentional/therapeutic use of acetaminophen, the ubiquitous detection of urinary concentrations of acetaminophen indicates the existence of possible unintentional (background) sources of exposure. The unintentional exposure may occur by direct ingestion of acetaminophen residues in food and water or through exposure to aniline, an important source material in the chemical industry that is converted in vivo to the analgesic. Data show that among different groups investigated for acetaminophen in the urine, pregnant women are those with the highest proportion of individuals with recent intentional use of acetaminophen. This may perhaps reflect the fact that acetaminophen is often recommended by doctors during all stages of pregnancy and, therefore, be perceived by the pregnant woman as a medication without risks (Kristensen et al., 2016). Research on the mechanism of analgesics is still too premature to

enable a precise explanation of their anti-androgenic action. There is for example, no clear association between analgesic suppression of testosterone and the analgesic-induced blocking of prostaglandin synthesis. This may suggest that alternative mechanisms could be involved and experiments using animal models and xenograft models of human testicular development have found that analgesics can have the ability to inhibit the expression of genes encoding steroidogenic enzymes and thereby inhibit androgen synthesis (Kristensen et al., 2016). It is obvious that the effects of prenatal analgesics exposure are much less severe than both thalidomide and DES. It is therefore likely that analgesics, unlike thalidomide and DES, will continue to play a vital role in the clinic for pregnant women in many years to come. It is, however, also clear that thalidomide, DES and analgesics all share the fact that they are drugs developed during the 18th and the first half of the 19th century prior to the thorough testing seen today.

Adult Exposure to Pharmaceutical Drugs and Reproduction

Multiple pharmaceutical drugs have been shown to affect fertility including exogenous hormones, antineoplastic drugs, psychotropic medications, antihypertensive medications and anti-infection medications (Samplaski and Nangia, 2015). These diverse drug effects can be classed in three groups based on their mechanisms of action: (i) disruption of the hypothalamic–pituitary–gonadal (HPG) hormonal axis; (ii) impairment of sperm production and function; (iii) or changes in sexual function including erections, ejaculation, and libido (Samplaski and Nangia, 2015). Among these groups, especially the investigation of impairment of sperm production and function is difficult due to the high variability in spermatogenesis. Healthy men not taking any medications exhibit daily, monthly and seasonal variations in sperm counts and motility and at the same time all the sperm parameters are highly dependent on the duration of abstinence prior to ejaculation. Moreover, the effects on fertility by many drugs is not well investigated or conflicting due to the above-mentioned limitations and the fact that the men are using the drugs for a reason. Hence, in human epidemiological studies focusing on side effects on reproduction, it is difficult to control for whether the underlying disease for which the drug is used also is changing for example the hormonal balance or spermatogenesis. The following will therefore summarize and highlight examples that are particularly adverse documenting the three above-mentioned groups.

Changes of the Hypothalamic–Pituitary–Gonadal Hormonal Axis

Exogenous male hormones, hormone substitutes and hormone antagonists all have potential negative impact on male fertility. Gonadotropin-releasing hormone, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone in the HPG axis are essential for the successful completion of spermatogenesis (see Fig. 1). All drugs containing male hormones or their derivatives have therefore potential to impair sperm proliferation and/or maturation, suppress spermatogenesis, and inhibit the testicular function through interfering with the balance of these essential hormones. A classic case of such disruption is exogenous testosterone used by a high number of men in their reproductive years to obtain a particular body figure or in the faulty belief that it enhances fertility (Samplaski and Nangia, 2015). Exogenous testosterone impairs spermatogenesis through suppression of the HPG axis through decreasing levels of FSH, LH and the endogenous levels of testosterone. In most cases, the spermatogenic arrest induced by exogenous testosterone is resolved by 4–12 months after cessation. Other common drugs with known effects on the HPG axis are opioids, shown to disrupt gonadotropin secretion from the hypothalamus, and mild analgesics that can decrease testosterone secretion from Leydig cells and hence reduce sensitivity to LH (De Maddalena et al., 2012; Albert et al., 2013; Kristensen et al., 2016).

Impairment of Sperm Production and Function

As mentioned above, exogenous hormones can induce spermatogenesis arrest through obstruction of the reproductive hormones under control of the HPG axis, as these hormones control the continuous cell proliferation and differentiation associated with spermatogenesis. However, drugs can also affect directly the spermatogenesis. Such effects have been reported for inhibitors of cyclic nucleotide phosphodiesterases (PDEs) that selectively catalyze hydrolysis of cAMP and/or cGMP. These inhibitors are used to promote an increase in cAMP and cGMP levels to increase endovascular smooth muscle relaxation for example the treatment of erectile dysfunction. Spermatogenesis is regulated through adenylate cyclase and other enzymes involved in the creation of cAMP, which play a vital role during early meiosis. It is therefore likely that PDEs interfere with sperm production by disrupting the balance of cAMP during spermatogenesis (Samplaski and Nangia, 2015). Antineoplastic drugs used in cancer treatment are another group of compounds with effects on male fertility. These drugs have the potential to damage both germ cells and the supporting Sertoli cells, resulting in severe oligozoospermia or azoospermia. The rapidly proliferating and differentiating spermatogonia are particularly sensitive to the actions of these compounds that are used in the clinic to target proliferating cancer cells. For example, busulfan, used for leukemia, is considered a direct sterilizing agent, as it kills the spermatogonial stem cells (Howell and Shalet, 2001). Other antineoplastic drugs do not cause azoospermia, or cause only temporary and/or modest reductions in the sperm counts because they kill only the differentiating spermatogonia. Another group of drugs known to affect fertility through effects on sperm are the anti-depressive drugs selective 5-hydroxytryptamine/serotonin re-uptake inhibitors (SSRIs). These drugs have been found to have a direct effect on sperm function due to oxidative phosphorylation of mitochondria or an effect on the sperm cell membrane.

Fig. 1 A major mechanism of pharmaceutical drugs resulting endocrine disruption in the adult male is the hypothalamic–pituitary–gonadal (HPG) axis that control sex hormones and spermatogenesis. The schematic representation show how drugs can interfere with this hormonal axis and directly spermatogenesis. *GnRH*, Gonadotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *ExoT*, exogenous testosterone; *DHT*, dihydrotestosterone; *PDEs*, phosphodiesterases; *SSRIs*, selective 5-hydroxytryptamine/serotonin re-uptake inhibitors; *5ARIs*, 5 α -reductase inhibitors.

A controlled trial have showed that SSRI use decreased motility and increased DNA damage in sperm cells as a function of duration of use. Hence, a study with 35 men taking SSRI for 5 weeks have shown that while using the SSRI mean sperm DNA fragmentation was higher (Tanrikut et al., 2010). Other compounds used in psychiatric care are opioids and these compounds have been shown to have similar effects as SSRIs including increased sperm DNA fragmentation.

Sexual Function Including Erections, Ejaculation, and Libido

Sexual function is obviously important for male fertility and important for these actions are testosterone and its derivatives. Of particular interest in this regard is the 5 α -reductase inhibitors (5ARIs) that block the conversion of testosterone to dihydrotestosterone (DHT). This conversion happens in certain tissues including the prostate gland, seminal vesicles, epididymis, skin, hair follicles, liver, and brain. Central for understanding the effects of DHT is that it is a more potent as an agonist of the androgen receptor (AR) than testosterone. 5ARIs are used for the treatment of benign prostate hyperplasia and male baldness through inhibition of two primary isozymes of 5 α -reductase, the enzyme converting testosterone to DHT (Samplaski and Nangia, 2015). The drug finasteride inhibits type II 5 α -reductase, while dutasteride inhibits both type I and type II 5 α -reductase. While conflicting data exist for the effects on spermatogenesis, effects on men after using 5ARIs and increased risk of sexual dysfunction are robust (see Fig. 1). This include erectile dysfunction, diminished sexual desire and ejaculatory dysfunction (Samplaski and Nangia, 2015). The sexual adverse effects of 5ARIs are thought to be caused by alterations in steroid levels in the cerebrospinal fluid. Hence, the fluid have been shown to be altered in men with persistent sexual adverse effects following finasteride use. In some men, the sexual dysfunction continues after cessation of 5ARI use and one study found persistent sexual dysfunction among 50% of affected patients following discontinuation of finasteride use (Wessells et al., 2003). Another class of common drugs with

known effects on libido, erectile dysfunction and ejaculatory dysfunction are psychotropic medications. Tricyclic antidepressants and selective SSRIs have shown to have these effects together with monoamine oxidase inhibitors and medications for bipolar conditions, such as lithium. These drugs have multiple action on the reproductive apparatus likely through anticholinergic, α -blocker and/or dopaminergic properties. Hence, where the 5ARI drugs interfere with HPG axis, the psychotropic drugs are believed to act primarily through changes of neurotransmitters in the CNS in such a way that the SSRIs are now used off-label by urologists for the treatment of premature ejaculation (Samplaski and Nangia, 2015).

Conclusions

As use of drugs become more and more common, it is likely that effects on male reproduction will become more pronounced. Although it is unlikely that the disastrous experiences after maternal use of thalidomide and DES will be repeated, recent years work on analgesics suggest that prenatal exposure to all drugs should be considered with concern. Obviously, human physiology is much more robust in adult life compared to the prenatal era. Nonetheless, the effects of drugs on the adult can be nothing but subtle as seen with young men using exogenous testosterone. The years to come will therefore undoubtedly show more cases of drugs obstructing male fertility.

Female reproduction is required for the continuity of life and preservation of the species. It also plays a major role in evolution by transmitting advantageous changes/variations from one generation to the next. Due to the vital roles of female reproduction, it is considered to be one of the most important systems in the body.

The female reproductive system includes the ovaries, oviducts, uterus, vagina, and mammary glands, as well as the placenta and fetus in pregnant animals. This system is primarily regulated by the hypothalamic-pituitary-gonadal (HPG) axis (Levine & Hadley, 2007). The hypothalamus is part of the brain and receives stimulatory and inhibitory signals from the brain and rest of the body as necessary. The pituitary consists of two lobes: the posterior pituitary and the anterior pituitary. The posterior pituitary is an extension of the hypothalamus and receives direct chemical signals from the hypothalamus. The anterior pituitary is not directly connected to the hypothalamus and receives hormonal signals from the hypothalamus via the hypophyseal portal vein to function properly. The ovaries have a dual function in the HPG axis: an endocrine function, producing and secreting hormones (steroidogenesis), and a nonendocrine function, developing and releasing germ cells for reproduction (gametogenesis). Through positive and negative feedback loops, the hypothalamus, pituitary, and ovaries work together to orchestrate the function of the female reproductive system.

Within the HPG axis, the hypothalamus produces gonadotropin-releasing hormone (GnRH), the anterior pituitary gland produces luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and the ovaries produce sex steroid hormones, including estrogens, progesterone, and androgens (Hirshfield, 1991; Levine & Hadley, 2007). GnRH from the hypothalamus directly stimulates secretion of FSH and LH from the anterior pituitary. FSH then stimulates folliculogenesis and steroidogenesis, and LH induces steroidogenesis, ovulation, and the development of the corpus luteum (Levine & Hadley, 2007).

The HPG axis is regulated and maintained by a balance of positive and negative hormonal feedback loops. This provides a delicate balance of stimulatory and inhibitory signals between the components of the axis. Thus, hormones secreted by the ovaries, specifically progesterone and estradiol, feed back on the hypothalamus and anterior pituitary and inhibit either GnRH or FSH and LH release, respectively. Without GnRH, FSH, or LH stimulation, hormones from the ovaries will not be secreted, releasing the negative feedback hold on the hypothalamus and pituitary and maintaining homeostasis.

The ovary is a complex tissue and is responsible for oocyte development and sex steroid hormone production (Hirshfield, 1991). The follicle is the functional unit of the ovary. Follicles are present within the ovary in various stages of development. Primordial follicles consist of a single germ cell, termed an oocyte, surrounded by a single layer of flattened somatic cells, known as granulosa cells. The primordial follicle develops into the primary follicle, which consists of an oocyte surrounded by a single layer of cuboidal granulosa cells. The primary follicle then develops into the preantral follicle, which consists of a single oocyte surrounded by at least two layers of granulosa cells and a newly formed theca cell layer. The final follicular stage is the antral follicle; this follicle has a single oocyte with multiple layers of granulosa cells, two theca layers (theca interna and theca externa), and a fluid-filled space called the antrum. The antral follicle is the only follicle in the ovary that can release an oocyte during ovulation, and it produces and secretes the majority of sex steroid hormones within the ovary. Once the oocyte has been ovulated, the follicle develops into a corpus luteum, a temporary endocrine gland responsible for making hormones that act on the brain and uterus to establish and maintain pregnancy.

Pregnancy is a complex event and involves fertilization, implantation, placentation, and development of the conceptus into a fetus (Spencer, Dunlap, & Filant, 2012; Wang, Wu, & DeMayo, 2017). During fertilization, the sperm cell penetrates the zona pellucida, a glycoprotein membrane that surrounds the oocyte. Fusion of the plasma membranes of the sperm and oocyte triggers the cortical reaction, which prevents other sperm from entering the oocyte. The union of oocyte and sperm occurs in the ampulla of the oviduct and marks the initiation of prenatal development. Implantation is the process by which the blastocyst attaches to the uterine lining. Implantation is divided into several stages: orientation, apposition and attachment (establishes contact with the uterus), adhesion (attaches to the luminal epithelium of the uterus), and invasion (penetrates the uterine stroma). This process is followed by placentation, during which time the placenta is formed to facilitate the transfer of maternal nutrients to the developing embryo. In several species such as the human and mouse, the stromal cells of the uterus undergo a process termed decidualization, which regulates development of the placenta, remodeling of the vasculature, and immune cells.

The end of pregnancy is marked by parturition and the birth of the offspring. In humans and several other mammalian species, labor is characterized by the sustained development of weak and irregular contractions of the uterus, which progressively become stronger and more coordinated. Finally, labor results in the expulsion of the fetus, placenta, and membranes. Prostaglandins and oxytocin are involved in the stimulation of uterine contractions, which are necessary for the progression of parturition (Vannuccini, Bocchi, Severi, Challis, & Petraglia, 2016). Prostaglandins synthesized by uterine decidual cells and the placenta act on the smooth muscle cells of the uterus. Prostaglandins, mainly prostaglandin $F_{2\alpha}$ (PGF_{2 α}) and prostaglandin E₂ (PGE₂), stimulate contraction of smooth muscle cells of the myometrium and promote the softening, dilation, and effacement of the cervix.

Prostaglandin synthesis by uterine myometrium is stimulated by oxytocin. Oxytocin is synthesized by neurons in the supraoptic and paraventricular nuclei of the hypothalamus, but it is stored in and released from the posterior pituitary. Oxytocin signals through its receptors in uterine smooth muscle cells to stimulate contractions and increase intrauterine pressure. Finally, contraction

of the myometrium is triggered by increases in intracellular calcium concentrations. Contraction is coordinated by formation of membrane channels known as gap junctions that allow rapid transfer of small molecules from cell-to-cell.

After birth, the mammary gland supplies a balanced mixture of nutrients, specifically tailored for neonatal health, growth, and development of the offspring (Neville, 1999). In humans, full development of the mammary glands during pregnancy is mainly governed by the actions of prolactin (PRL), estrogen, and progesterone. Prolactin is made by lactotrophs within the anterior pituitary, and its release is constantly inhibited by dopamine (DA). The main functions of PRL are to promote mammary growth, initiate milk secretion, and maintain milk secretion once it is established. PRL binds to PRL receptors (tyrosine kinase receptor type) present in the breast and stimulates the expression of milk protein genes, such as casein and lactalbumin. To nourish the offspring, milk must be successfully ejected from the breast, and this process is governed by oxytocin, which stimulates contraction of the myoepithelial cells surrounding the alveoli and ducts of the breast. Suckling stimulates both PRL and oxytocin release via neural pathways. Specifically, these pathways inhibit dopaminergic neurons in the median eminence of the hypothalamus to stimulate the release of PRL, whereas they stimulate neurons to release oxytocin.

Offspring progress through puberty and become capable of reproduction themselves. Eventually, the reproductive life span will end and the organism will undergo reproductive senescence. The timing of puberty and the onset of reproductive senescence can vary considerably between species and in response to environmental exposures (Gore et al., 2015).

In conclusion, female reproduction is complex and involves many organs and hormones (Gore et al., 2015; Hirshfield, 1991; Levine & Hadley, 2007; Neville, 1999; Spencer et al., 2012; Vannuccini et al., 2016; Wang et al., 2017). This volume highlights the major organs, hormones, and processes that control female reproduction. It contains several chapters on various aspects of the ovary, including ovarian development, folliculogenesis, steroidogenesis, ovulation, and corpus luteum formation. Further, this volume contains several chapters on the hypothalamus and pituitary, as well as hormones that are produced by or regulate the hypothalamus and pituitary. This volume also contains several chapters on other important female reproductive organs such as the oviducts, uterus, cervix, vagina, placenta, and mammary glands. Further, this volume contains several chapters on pregnancy, including the endocrinology of pregnancy, pregnancy complications, parturition, labor, and delivery. It also contains several chapters on important physiological events in female reproduction such as puberty, menopause, and reproductive senescence. Finally, this volume includes chapters on female reproduction in multiple species, and it provides several chapters on the impacts of environmental chemicals on female reproduction.

Glossary

Corpus luteum An endocrine gland formed from the granulosa and theca layers of an ovulated follicle.

Follicle A structure in the ovary consisting of the oocyte and surrounding granulosa and theca cell layers.

Granulosa cells Somatic cells directly surrounding the oocyte.

Meiosis A type of cell division which the oocyte undergoes reducing the number of chromosomes so that the oocyte has one copy of each chromosome.

Oocyte The female gamete.

Ovary The female gonad.

Steroids Molecules with a basic structure similar to that of cholesterol.

Theca cells Layer of steroidogenic cells and connective tissue surrounding the granulosa cells and forming the outer layer of the follicle.

Introduction

Ovaries are female gonads responsible for the generation of female gametes (oocytes) and synthesis of hormones necessary for the regulation of reproductive functions. Since the first description of the ovary reported by Aristotle more than 2000 years ago, information about the ovary has expanded significantly. Knowledge of the formation of the ovary and its endocrine function is essential to understand the mystery of the regeneration of life.

Anatomy of the Ovary

Most vertebrates develop a pair of ovaries with the exception of some birds, reptiles and a few mammals that only have one ovary. Ovaries lie on either side of the upper pelvic cavity and against the pelvic wall. They are held in place by a mesentery (mesovarium) connected to a broad ligament. Ovaries are one of the most vascular organs in the body. The ovarian artery (or utero-ovarian artery) which arises from the abdominal aorta reaches the ovary along with the mesovarium. Branches of the ovarian artery enter the ovary through the hilus, the same site at which the venous blood exits. Adrenergic and cholinergic nerves also enter the ovary through the hilus.

Even though the size of the ovary varies, the structure of the ovary is similar among mammalian species (**Fig. 1**). The ovary consists of an inner medulla, containing a rich vascular bed within loose connective tissue and an outer cortex, where the ovarian follicles are located. The outermost layer of the cortex is a single squamous or cuboidal surface epithelium derived from the peritoneum. Under the surface epithelium lies the tunica albuginea, a poorly delineated layer of dense connective tissue that gives the ovary a whitish color. The cortex of the ovary is made up of numerous follicles of various sizes and stages of development embedded in the stroma. The stroma is composed of at least three different cell types: connective tissue cells (fibroblasts) performing support functions, smooth muscle cells regulating the contraction of blood vessels and interstitial cells including undifferentiated theca cells and degenerated cells from atretic follicles and regressed corpora lutea. The follicles (follicle is Latin for "little bag") are structurally very conspicuous because of their variation in size. The microscopic appearance of follicles is different depending on the stage of follicular development whereas the basic cellular organization of follicles is the same. A follicle consists of an oocyte and surrounding follicular wall. Between the oocyte and surrounding follicular wall is a thin transparent membrane, the zona pellucida. The follicular wall contains an inner granulosa layer and an outer theca layer. The granulosa layer surrounds the oocyte and is separated from the theca layer by the basement membrane. The number and function of the granulosa cells changes during follicular growth. In mature follicles, the theca layer can be divided into the theca externa and interna. The theca externa consists of concentrically arranged smooth muscle cells innervated with autonomic nerves. The theca interna has epithelioid cells called interstitial cells, which are steroid producing cells. These cells contain LH and insulin receptors

Fig. 1 A cross-section of the ovary illustrating follicles at different stages of development (from primordial to Graafian follicles), corpus hemorrhagicum, corpus luteum, and corpus albicans. The microscopic structures of follicles are also shown. Adapted from Jones, R.E. (1991) *The ovaries in human reproductive biology*, pp. 39–53. Academic Press, San Diego. p. 42.

and synthesize primarily androgens, of which the predominant steroid is androstenedione. The theca interna has both blood vessels and nerves. The granulosa layer is devoid of blood vessels and nerves at all times.

Once ovulation of the Graafian follicle (tertiary) has occurred, blood derived from torn blood vessels of the theca layer infiltrates the collapsed follicle and results in the formation of the corpus hemorrhagicum, a developing corpus luteum with a bloody core. Luteinizing granulosa and thecal cells begin to divide and invade the antral cavity, which remains after ovulation of the oocyte, forming the corpus luteum (Latin for “yellow body”). Blood vessels from the theca layer grow and penetrate the developing luteal cell mass. If pregnancy does not occur, the corpus luteum degenerates after a certain length of time depending upon the species. The connective tissues replaces the luteal cells and forms the corpus albicans (Latin for “white body”). The ovarian medulla devoid of follicles, contains large, spirally arranged blood vessels, lymphatic vessels and nerves.

Functions of the Ovary

Generation of the Female Gametes

Oogenesis

Female gametes, or oocytes, provide the maternal genetic material for the formation of an embryo. The ovary nurtures thousands of oocytes and functions as an incubator for their development. The development of oocytes (oogenesis) starts with primordial germ cells, residing in sex cords which divide mitotically producing oogonia. Oogonia then become primary oocytes and undergo the first meiosis. The primary oocytes are arrested at the diplotene stage of the first meiosis until they experience the preovulatory LH surge. Then the first meiosis is reinitiated and the membrane of the oocyte nucleus (germinal vesicle) disintegrates, which is called germinal vesicle breakdown. Meiosis of the oocyte is unequal producing a large haploid secondary oocyte and a tiny haploid first polar body. This polar body can divide again or remain single; in either case, it degenerates. Then the secondary oocyte begins the second meiotic division but this division is arrested at metaphase until after sperm penetration of the oocyte, which occurs in the oviduct. Completion of the second meiosis results in a haploid ovum and the second polar body.

Folliculogenesis

Folliculogenesis is a developmental sequence regulated by a number of genes, transcription factors and hormones. During fetal development of humans and postnatal development of mice, oocytes are present in clusters or nests. Majority of these oocytes enter meiosis during embryonic life. As the oocytes separate into individual oocytes, they form primordial follicles and undergo further development called oogenesis. Maturation of oocytes (oogenesis) is closely associated with the development of follicles because factors produced by the oocytes have a major impact on the development of the granulosa and theca layers. Folliculogenesis always begins in the innermost part of the ovarian cortex in mammals. Primordial follicles consist of primary oocytes surrounded by flat squamous pre-granulosa cells. Primordial follicles are the only available source of oocytes during the entire reproductive period of the female. As primordial follicles develop into primary follicles, there are changes in the oocyte. It

increases in diameter and develops an extracellular matrix, the zona pellucida. Reactivation of the oocyte genome causes the oocyte to secrete growth factors which play a crucial role in the growth of the follicle. As primary follicles grow, the granulosa cells divide mitotically so that secondary follicles have two to six layers of cuboidal-shaped granulosa cells. Secondary follicles also acquire an additional somatic cell layer, the theca. There are at least two sources of the theca progenitor cells: somatic precursors of the fetal ovary and mesenchymal cells in the neighboring mesonephros. The formation of this theca layer is dependent upon the presence of growth differentiation factor-9 (GDF-9) produced by the oocyte. The theca layer forms around the basement membrane in secondary follicles and ultimately forms the theca interna and theca externa. Follicular growth from primordial to secondary follicles is gonadotrophin-independent. During the formation of tertiary follicles or preantral follicles, follicles continue to grow in size. As follicles progress from secondary follicles to antral follicles, granulosa cells secrete a fluid that accumulates between cells. Large amounts of additional fluid diffuse out of the thecal blood vessels and are added to the fluid which is called follicular fluid. Follicular fluid contains steroid and protein hormones, anticoagulants, enzymes, and electrolytes and is similar to blood serum in appearance and contents. The follicle filled with follicular fluid is the tertiary or preovulatory follicle. These follicles have a mural granulosa layer of four to six layers and the theca layer is differentiated into an inner theca interna and an outer theca externa. Oocytes in preovulatory follicles are suspended in follicular fluid by a stalk of granulosa cells, the cumulus oophorus. Immediately surrounding the oocyte is a thin ring of granulosa cells, the corona radiata. At this state the follicle is called the Graafian follicle and appears as a transparent vesicle that bulges from the surface of the ovary.

Even though one of the function of the ovary is to produce oocytes, the majority of oocytes never ovulate. The number of oocytes reaches its maximum soon after the ovaries are formed. After that time oocyte number decreases dramatically. At birth, a female has all the oocytes she will have in her life; no new oocytes are formed after birth. The vast majority of oocytes, enclosed in follicles, around 99.9%, are eliminated before ovulation through a process called atresia which is due to the activation of apoptosis in the oocyte and granulosa cells. Follicles can become atretic at any stage of development.

Production of Hormones

Another function of the ovary is to secrete hormones which act on the hypothalamus and pituitary to regulate the secretion of hormones by these two tissues, thus establishing the hypothalamic-pituitary-ovarian axis. The ovarian hormones also regulate the function of the reproductive tract and ultimately reproduction.

Protein and peptide hormones

- (i) *Inhibin and activin*: Inhibin and activin were first isolated from gonadal fluids because of their effects on production of follicle stimulating hormone (FSH) by the pituitary in mammals. Inhibins consist of two disulfide-bridged subunits, the α and β subunits, whereas activins consist of two β subunits. The primary source of inhibin and activin in the ovary is the maturing follicles and the corpus luteum. The function of inhibins is to modulate FSH secretion at the level of the pituitary, whereas the function of activins is to increase FSH secretion at the level of the pituitary. Inhibins and activins have antagonistic actions. Inhibins and activins also function as intraovarian hormones.
- (ii) *Follistatin*: Follistatin is a FSH-modulating polypeptide not related to TGF- β . Follistatin acts as a binding protein and a functional antagonist of activin. Granulosa cells in antral follicles and luteal cells secrete follistatin.
- (iii) *Relaxin*: Relaxin is produced by the corpus luteum. The structure of relaxin is very similar to that of insulin but has <20% amino acid homology. In the human, relaxin is the highest during the first trimester of pregnancy after which the concentrations are relative stable. In the rat and the pig, relaxin reaches the highest concentration prior to parturition. Relaxin in these species functions to soften the cervix and vagina for the passage of the fetus during parturition and to promote the growth of nipples. Relaxin also acts on nonreproductive tissues, such as skin and the gastrointestinal tract.
- (iv) *Growth factors*: The ovary not only secretes endocrine hormones to regulate functions of other reproductive organs but also produces growth factors to coordinate the activities of different ovarian compartments. Many growth factors, such as insulin-like growth factors, transforming growth factors and epidermal growth factor are produced by the oocyte and somatic cells in the ovary. This complex intraovarian regulation system is no less important than the extraovarian regulation by the pituitary hormones. These growth factors form a delicate interactive communication web inside the ovary. Without them, the ovarian cells cannot interact with each other and the growth of the ovary is halted.

Steroid hormones

The ovary uses cholesterol as the precursor for steroid synthesis. Cholesterol is metabolized into progestins, androgens, and estrogens by different compartments of the follicles (Fig. 2).

- (i) *Progestins pregnenolone*. Is the most important progestins (C21 pregnane family) produced by follicles because of its key position as the precursor of all steroid hormones. The most abundant progestin is progesterone, produced as a biosynthetic intermediate by follicles at all growing stages of development and as a secretory end product of the corpus luteum. In the developing follicles, the theca layer is the primary site of progestin productions. Immediately prior to ovulation, the granulosa cells stimulated by LH also synthesize progesterone. After ovulation the corpus luteum

Fig. 2 Biosynthesis of steroid hormones from cholesterol. This scheme provides a simplistic view of a highly organized and complicated process that requires multiple enzymes. Adapted from Hafez, E.S.E (1993) Folliculogenesis, egg maturation, and ovulation. In *Reproduction in farm animals*, 6th ed., pp. 114–143. Lea and Febiger, Philadelphia, p. 79.

synthesizes copious amounts of progesterone needed to prepare the uterus for implantation and later for the maintenance of pregnancy.

- (ii) **Androgens.** The follicle is a significant source of ovarian androgens (C19 androstane family). Pregnenolone and progesterone are converted into androgen metabolites, dehydroepiandrosterone and androstenedione, respectively. These two metabolites are then transformed into testosterone. The theca layer of the follicle is the primary source of ovarian androgens.
- (iii) **Estrogens.** Physiologically, the estrogens (C18 estrane family) especially estrone and estradiol-17- β , are the most important of the ovarian steroids. Androstenedione and testosterone are the immediate biosynthetic precursors of estrone and estradiol-17- β , respectively. Their names reflect their roles in the induction of sexual receptivity (estrus) in female mammals. Estrone was the first sex steroid isolated and identified. The granulosa layer is the major site of estrogen synthesis in the mammalian ovary.

Regulation of Ovarian Functions

Regulation of Folliculogenesis

Growth of primordial follicles to the preantral stage is independent of gonadotropins and is controlled by intraovarian growth factors. Growth of follicles after the preantral stage depends on appropriate patterns of secretion, sufficient concentrations and adequate ratios of FSH and LH in the blood. FSH plays a major role in early follicular development. FSH stimulates granulosa cell mitosis and accumulation of follicular fluid. Granulosa cells synthesize estrogens in response to FSH which further enhance the mitotic effect of FSH. Moreover, FSH induces granulosa cell sensitivity to LH by increasing LH receptor expression. Abundant LH receptors in granulosa cells prepare the luteinization of granulosa cells in response to the ovulatory LH surge in mammals. In contrast, theca cells are stimulated only by LH and LH receptors are present from the beginning of the formation of the theca layer.

Fig. 3 “Two-cell, two-hormone” theory of follicular steroidogenesis. LH binds to specific membrane receptors on theca cells and stimulates cyclic AMP production and the conversion of cholesterol to androgens, primarily androstenedione and testosterone. These androgens diffuse into the circulation and across the basement membrane into granulosa cells. FSH binds to specific membrane receptors on granulosa cells and stimulates cyclic AMP production, which leads to increased aromatase enzyme activity and the conversion of theca androgens to estrogens. Adapted from Yen, S. S. C. and Jaffe, R. B. (1986). *Reproductive Endocrinology* (2nd ed.), Philadelphia: Saunders.

Regulation of Steroidogenesis

The steroidogenic output of the ovary is a function of coordinated actions of theca and granulosa cells. Differences in gonadotropin receptors on the membrane, in the activity of steroidogenic enzymes and in compartmentalization in the follicle result in a unique partnership in steroid synthesis between theca and granulosa cells. The principal site of estrogen synthesis in the mammalian ovary is granulosa cells under the control of FSH. Androgen production appears to be the primary steroidogenic function of theca cells in response to LH. Androgens from theca cells provide substrates for granulosa cells to synthesize estrogens. The action of LH on theca androgen production, together with the action of FSH on granulosa estrogen synthesis, forms the basis of the “two-cell, two-hormone” theory for the control of steroidogenesis in the ovary (Fig. 3).

Granulosa Cells

Sarah C Baumgarten and Carlos Stocco, University of Illinois College of Medicine, Chicago, IL, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Granulosa cells, their precursors, or their final differentiation stages are critical components of the ovary that nurture germ cells, sustain oocyte maturation, provide the hormonal milieu required to synchronize uterus receptivity with the release of the mature eggs, and support early pregnancy. Granulosa cells are the only somatic cells that closely interact with the oocyte from the moment the follicle forms until the release of the oocyte at ovulation. Throughout this long relationship, both the oocyte and the granulosa cells go through significant functional and morphological changes.

Embryonic Progenitors

Pregranulosa cell differentiation is vital for fertility because it ensures the differentiation of the oogonia, the formation of the definitive follicle reserve, and, ultimately, the formation of the ovary. Pregranulosa cells originate from coelomic proliferating epithelial cells that proliferate and invade the developing gonads. Pregranulosa cells can be classified into medullary and cortical cells depending on their location in the developing gonad. Some precursor cells migrate to the medulla of the fetal gonads at approximately embryonic day 11.5 (E11.5) in the mouse and are known as medullary cells. These cells stop proliferating and get incorporated into medullary follicles. A second population of precursors enters the ovary from the epithelium between E15.5 and postnatal day 4 and remains closer to the ovarian surface and is, therefore, called cortical cells. Some of these cortical cells also stop proliferating, differentiate into pregranulosa cells, and get incorporated into cortical primordial follicles a few days after birth in the mouse. The follicles in the medulla of the ovary are activated immediately after birth and reach antral stages before puberty, whereas cortical follicles are activated throughout the reproductive years of the female (Zheng et al., 2014).

Pregranulosa cells can be recognized by the expression of forkhead box L2 (FOXL2) and LGR5. FOXL2 is a forkhead transcription factor expressed not only in medullary pregranulosa cells in the developing XX gonad but also in mature granulosa cells. Recently, the adult stem cell marker LGR5 was found to be expressed in the cortical region of the fetal ovary in cells that give rise to adult cortical granulosa cells. LGR5 binds R-spondin proteins with high affinity and thereby enhances WNT signaling. *Lgr5* deletion blocks germ cell differentiation (Fig. 1, pregranulosa cell differentiation).

The commitment of the coelomic proliferating epithelial cells that invade the developing gonads to the granulosa fate defines sex determination. Thus, if these cells have a Y chromosome and express SRY and SOX9, the gonad develops into a testis. In the absence of SRY and SOX9, the expression of female-specific genes encoding secreted factors such as R-spondin1 (RSPO1), WNT4, and follistatin and transcription factors such as GATA4, β -catenin, and FOXL2 triggers ovarian development and actively suppresses testis differentiation. Of these genes, *Rspo1* and *Wnt4* are already expressed in the bipotential gonad, but they become ovary-specific at E11.5. WNT4 and RSPO1 are parts of a common signaling pathway that acts through β -catenin, which is essential for pregranulosa cell differentiation.

The transcription factors GATA4 and GATA6 are also present in the pregenital ridge region as early as E10. Both factors are required for the proliferation of the coelomic epithelium leading to the formation of the genital ridge. GATA4 remains expressed at E11.5 in the primitive gonads of both XX and XY mouse embryos. By E13.5, GATA4 is found in most ovarian somatic cells where it is expressed at high levels over the entire fetal period. In animals that lack GATA4 and GATA6 during embryogenesis, the expression of key markers of pregranulosa cells, including FOXL2, is reduced leading to a decrease in proliferation and an increase in apoptosis. In mice lacking GATA, the majority of the oocytes are lost after birth due to the lack of granulosa cell support.

Fig. 1 Genes involved in pregranulosa cell differentiation. During embryonic gonad development, the ovary-specific genes *Foxl2*, *Rspo1*, *Wnt4*, and β -catenin suppress the male pathway through inhibition of *Sox9*. In the adult ovary, FOXL2 and ESR1 are required for tissue maintenance and follicle maturation.

Follicle Assembly

Once primordial germ cells arrive at the developing gonad, they stop migrating but continue dividing. At this point, these cells are known as oogonia. Due to incomplete cytokinesis, oogonia remain attached in clusters forming cysts or nests that become enclosed by somatic pregranulosa cells. The oogonia continue dividing until they receive signals from surrounding somatic and pregranulosa cells to shift from mitosis to meiosis. It is clear that the signal received by the oogonia to enter meiosis is dependent on the genomic sex of the surrounding cells. In fetal testis, primordial germ cells stop mitotic division and enter a period of mitotic quiescence in G₀. In the ovary, retinoic acid (RA) produced, in part, by the pregranulosa cells is responsible for inducing meiosis.

Under the influence of RA, clusters of oogonia enter meiosis synchronously, becoming oocytes. Later, the clusters break down, and individual oocytes become surrounded by squamous pregranulosa cells forming primordial follicles, which are the basic functional units of the ovary. This represents the first stage of folliculogenesis taking place during the latter half of fetal development in humans or during the days following birth in mice. In animals lacking factor in the germ line (FIGL α), pregranulosa cells fail to form a monolayer around individual primordial oocytes resulting in rapid oocyte loss. Similarly, mice lacking Notch2 signaling in the pregranulosa cells fail to break down the clusters of oogonia and form primordial follicles containing multiple oocytes.

Importantly, all granulosa cells in the postnatal ovary, in both the medullary and cortical follicles, are marked by the expression of FOXL2. Moreover, postnatal deletion of FOXL2 or estrogen receptor alpha (ESR1) induces a transdifferentiation of granulosa cells to sertoli-like cells, indicating that FOXL2 acts as an antitestis factor and is required to maintain the granulosa cell phenotype.

Gonadotropin-Independent Activation and Growth

Activation

The pregranulosa cells and the oocytes of cortical primordial follicles remain dormant for months in rodents or for decades in humans. Primordial follicles then transition to primary follicles. During this transition, the single layer of flattened granulosa cells changes morphology to become cuboidal granulosa cells. Primordial follicle activation occurs independently of pituitary gonadotropins. Instead, it is regulated by factors produced within the ovary and requires the interaction between pregranulosa cells and oocyte.

In FOXL2-null mice, granulosa cells remain flattened resulting in the absence of follicle growth suggesting that the activation of these cells in adult ovaries requires FOXL2. Similarly, inhibition of mTORC1 in granulosa cells blocks dormant follicle activation, while its overactivation increases this process. These findings indicate that granulosa cells play a major role in the activation of primordial follicles. An interaction between the flattened granulosa cells and the oocyte is also critical for follicle activation and is carried out by the KIT and KIT ligand (KITL) system. The oocyte expresses KIT, a tyrosine kinase receptor, on its surface, whereas flattened granulosa cells and later the granulosa cells express KITL, which is able to bind to KIT to promote follicle activation. Preventing KIT/KITL interaction in mice pauses follicle growth at the primordial stage, and few, if any, follicles transition to the primary stage. On the other hand, *in vitro* experiments demonstrated that if ovaries are treated with KITL, a significant number of follicles transition from the primordial to the primary stage (Saatchioglu et al., 2016; Zhang and Liu, 2015). However, the molecular changes involved in the transition from flattened to cuboidal granulosa cells remain to be determined.

Proliferation to Preantral Stage

As the ovarian follicle progresses from the primary stage to the preantral stage, the layer of cuboidal granulosa cells proliferates to form multiple layers. Granulosa cell proliferation occurs independently of gonadotropins. However, it is possible that the oocyte influences proliferation. Thus, mouse studies demonstrated that oocytes from follicles with two layers of granulosa cells could stimulate granulosa cell proliferation and differentiation in primordial follicles, suggesting that oocyte-secreted factors are crucial for follicle growth. One such factor is growth differentiation factor 9 (GDF9). For instance, folliculogenesis is arrested at the primary stage in animals lacking GDF9. Direct communication between the granulosa cells and the oocyte is also essential for follicle maturation beyond the primary stage. For instance, knockout of connexins 43 and 37 (CX43 and CX37), which both are components of gap junctions between the oocyte and surrounding granulosa cells, halts folliculogenesis at the primary (unilaminar) stage, and granulosa cell differentiation is impaired. The full spectrum of molecules and signals that travel through gap junctions to promote follicle growth remains to be determined.

Differentiation to the Preovulatory Stage

During follicle progression from the preantral to the preovulatory stage, a fluid-filled cavity called the antrum forms within the follicle. This final period of follicle growth is mainly driven by the expansion of the fluid inside the antrum than by the proliferation of the granulosa cells. Antrum formation depends on gonadotropins, which stimulate the production and secretion of polysaccharides and proteins by the granulosa cells. Granulosa cells produce and secrete hyaluronan and versican, a chondroitin sulfate proteoglycan, toward the extracellular space. The accumulation and the cross-links of these molecules generate an osmotic gradient, which in turn draws in fluid from the thecal vasculature. This idea is supported by genetic models. For instance, in animals lacking

Fig. 2 Changes taking place in granulosa cells (GCs) during folliculogenesis. The progression of follicles from the primordial to the preantral stage is dependent on intraovarian factors and does not require gonadotropins. The processes of antrum formation and granulosa cell differentiation to the preovulatory follicle stage are regulated by FSH. Ovulation and luteinization are controlled by LH.

GATA4 and GATA6 in the granulosa cells, versican expression is abolished in the granulosa cells, an effect that correlates with the lack of antrum formation.

The antrum physically separates the granulosa cells into two functionally distinct cell populations, cumulus and mural. The cumulus granulosa cells surround the oocyte and actively participate in oocyte maturation. The mural granulosa cells are close to the follicle wall and are the primary site of sex steroid hormone synthesis and produce estradiol as the follicle matures to the preovulatory stage (Fig. 2).

While intraovarian factors are the primary regulators of preantral granulosa cell growth, extraovarian factors, in particular follicle-stimulating hormone (FSH), are crucial for the differentiation of mural granulosa cells. This is illustrated in female FSH knockout mice, where folliculogenesis is halted at the preantral stage. Although FSH is essential for the survival, proliferation, and differentiation of preovulatory mural granulosa cells, local factors such as the insulin-like growth factor (IGF) system are also crucial for mural granulosa cell differentiation. Thus, granulosa-cell-specific IGF1R-depleted mice are infertile and lack mural cells.

Cumulus Cells

In antral follicles, cumulus granulosa cells remain intimately associated with the oocyte. The first layer around the oocyte is called the corona radiata. Both corona cells and cumulus cells in outer layers communicate with the oocyte via extensions that reach around the corona cells to contact the oocyte. Oocyte-secreted factors (OSFs) play crucial roles in the development and function of the cumulus cells.

Two well-recognized OSFs involved in cumulus cell regulation are growth differentiation factor 9 (GDF9) and bone morphogenetic protein 15 (BMP15). GDF9 and BMP15 protect cumulus cells from FSH-induced differentiation, and an opposing gradient of FSH and OSF signaling throughout granulosa cell layers establishes the cumulus or the mural phenotypes in vivo (Diaz et al., 2007). In mice, GDF9 and BMP15 activate SMAD2/3 signaling within the granulosa cells, which prevents FSH from stimulating genes expressed in mural granulosa cells, including luteinizing hormone (LH) receptor. Importantly, FSH cannot stimulate the expression of steroidogenic genes in the presence of SMAD2/3 activation, so cumulus cells are functionally distinct from mural granulosa cells and do not serve as a source of steroid hormone production during follicle maturation.

In humans, cumulus cells isolated from in vitro fertilization patients also express lower levels of differentiation markers than mural cells including CYP19a1, CYP11a1, StAR, and LH receptor indicating that cumulus cells are also protected from

differentiation in humans. Moreover, once separated from the oocyte, human cumulus cells respond to FSH with the activation of a genomic program that resembles the transformation of preantral to mural cells observed in laboratory animals. Thus, human cumulus granulosa cell cultures can serve as an experimental approach to study the differentiation of these cells. This has allowed for the identification of key genes and mechanisms of differentiation that were previously unable to be studied in humans (Stocco et al., 2017).

Cumulus granulosa cells nurture the oocyte by providing specific amino acids, glycolysis products, and cholesterol biosynthesis substrates via gap junctions. Additionally, cumulus granulosa cells prevent premature oocyte maturation and resumption of meiosis in the oocyte. The oocyte remains paused at the prophase stage of meiosis I throughout follicle maturation until shortly before ovulation. The pause in meiosis is sustained by cAMP within the oocyte. In a normal follicular cycle, the gonadotropin surge that triggers ovulation also stimulates the activation of phosphodiesterases within the oocyte that reduces the levels of cAMP and allows for the resumption of meiosis. Before the LH surge, cAMP levels in the oocyte are maintained through an intimate interaction between the oocyte and surrounding cumulus granulosa cells via gap junctions. In this system, the cumulus granulosa cells express NPR2, a receptor with guanylyl cyclase activity. Mural granulosa cells produce the ligand NPPC, which is released and can activate NPR2 on cumulus cells. When activated, NPR2 increases intracellular levels of cGMP, which travels into the oocyte through gap junctions. In the oocyte, cGMP inhibits the activity of phosphodiesterases to maintain cAMP levels. Interestingly, oocyte-secreted factors, such as GDF9 and BMP15, can enhance NPR2 expression in cumulus cells, thus enhancing the system necessary to maintain its pause in meiosis I (Egbert et al., 2016).

Cumulus expansion

A distinctive characteristic of cumulus cells is their capacity to change from a compact cell mass into a dispersed structure of cells during the preovulatory period. This process is referred to as cumulus expansion and involves the synthesis and deposition of a mucoid intercellular matrix. Cumulus expansion influences a variety of developmental changes during oocyte maturation.

Cumulus granulosa cells express very low levels of LH receptor compared with mural granulosa cells; however, the LH surge drives the process of cumulus cell expansion. In vitro studies have shown that the effect of LH on cumulus cells is mediated by mural granulosa cells. Upon LH stimulation, the mural cells produce epidermal growth factor (EGF)-like family members, which are released and activate the EGF receptor on cumulus cells to enhance expression of genes necessary for the formation and stabilization of ECM and cumulus expansion. Interestingly, cumulus expansion in response to EGF receptor activation also requires the presence of factors secreted by the oocyte. The expression of several genes including *Has2*, *Ptgs2*, *Ptx3*, and *Tnfaip6* are needed for cumulus expansion, and their deletion impairs this process.

Mural Cells

During the transition from the preantral to the preovulatory follicle, the granulosa cells that line the wall of the follicle and are distant from the oocyte differentiate into mural granulosa cells under the influence of FSH and locally produced factors such as IGFs. FSH stimulates the expression of hundreds of genes, including those necessary for the production of estradiol and expression of the LH receptor. FSH activates the FSH receptor, a G-protein-coupled receptor, on the surface of mural granulosa cells. This stimulates an increase in intracellular cAMP and PKA activation, finally resulting in the activation of CREB transcription factor. Many key genes for steroidogenesis are regulated by CREB, including aromatase. Additionally, FSH activates AKT signaling, which is essential, although not enough, to promote the expression of differentiation genes in granulosa cells (Fig. 3, cumulus and mural granulosa cell differentiation and function).

As mentioned earlier, the IGF family is also essential for the differentiation of mural granulosa cells. IGF1 and IGF2 and their target receptor, the IGF1R, are needed for the stimulation of AKT by FSH. In vitro studies in rodents and humans demonstrated that granulosa-cell-produced IGFs are essential for differentiation. Activation of the IGF1R by IGFs and subsequent AKT activation is needed for FSH to maximally stimulate the expression and activity of aromatase to enhance estradiol production. Interestingly, IGF production is species-specific. Thus, rodent granulosa cells produce IGF1, while human granulosa cells produce only IGF2. However, their role in granulosa cell differentiation is comparable.

Steroidogenesis

Antral follicles begin producing increasing levels of progestins, estrogens, and androgens. The mural granulosa cells and the adjacent theca cells surrounding the ovarian follicle are the sites of steroidogenesis. According to the “two cell theory” of steroidogenesis, the cells work cooperatively to produce estradiol. The theca cells express enzymes necessary for androgen synthesis, while the mural cells express aromatase, which converts androgens to estradiol. Theca cells produce androgens by expressing 17 α -hydroxylase/17,20-lyase (CYP17A1). This enzyme is not expressed in granulosa cells. However, the granulosa expresses StAR, CYP11A1, and 3 β -HSD. Therefore, they are able to produce progesterone.

Aromatase (CYP19A1) is the main steroidogenic enzyme expressed in mural granulosa cells. The timely expression of aromatase in the ovarian follicle is responsible for the cyclic changes in serum estradiol levels. These changes modulate the structure and function of the female reproductive tract, including the oviducts, the uterus, and the vagina. These endocrine actions are essential for oocyte survival, fertilization, and implantation. More importantly, the strong expression of aromatase and subsequent high level of estradiol production in preovulatory follicles lead to the surge of LH required to trigger ovulation. Locally produced estrogens also stimulate granulosa cell proliferation and facilitate FSH and LH actions in a paracrine/autocrine manner. Therefore, the

Fig. 3 Granulosa cell differentiation. As antral follicle development proceeds, mural granulosa cells and cumulus granulosa cells develop distinguishing characteristics. FSH drives the differentiation of mural granulosa cells, whereas the oocyte and oocyte-secreted factors (OSFs) actively prevent this in cumulus granulosa cells. Mural cells express genes involved in estradiol production and on the preparation of the cells for ovulation and luteinization. Oocyte-secreted factors stimulate the expression of cumulus cell-specific genes required to cumulus expansion and oocyte maturation.

well-timed and cell-specific expression of aromatase in mural granulosa cells is crucial for the autocrine regulation of folliculogenesis, the endocrine control of the female reproductive tract, and the coordination of gonadotropin secretion.

Ovulation

The high level of estradiol produced by the developing dominant follicle exerts a positive feedback on the anterior pituitary resulting in a surge of FSH and LH production and release into the circulation. This surge in LH acts on mural granulosa cells, which express high levels of the LH receptor, to initiate a series of events leading to cumulus cell expansion and follicle rupture. During this time, LH also stimulates the resumption of meiosis in the oocyte. Although the mechanisms are not entirely clear, a closure in gap junctions between the cumulus cells and oocyte or an increase in phosphodiesterase activity within the oocyte could contribute to a fall in cAMP and resumption of meiosis.

LH receptor activation in the preovulatory granulosa cells results in the induction of a broad range of genes that are crucial for ovulation and differentiation of the granulosa cells. Some of these genes are transiently induced, whereas others remain constitutively expressed in luteal cells. The transiently induced genes include progesterone receptor (*Pr*), cyclooxygenase (*Cox2*), CCAAT/enhancer-binding protein β (*C/EBP β*), and early growth response protein-1 (*Egr-1*). Mice deficient in *PR*, *C/EBP β* , or *COX-2* are infertile because preovulatory follicles fail to ovulate. LH also enhances the transcription of proteases, including matrix metalloproteinases (MMPs) and *Adamst1*, which degrade components of the surrounding ECM during the process of ovulation. This remodeling is essential for follicle rupture and release of the cumulus-oocyte complex from the ovary.

Final Differentiation: Luteinization

Mural and cumulus cells have different destinies after the preovulatory surge of LH. The mural cells remain in the ovary, luteinize, and participate in the formation of the corpus luteum, whereas the expanded cumulus cells accompany the metaphase II (secondary) oocyte to the oviduct. During luteinization, the granulosa cells express high levels of *StAR*, *CYP11a1*, and 3β -HSD, which are needed for the production of progesterone. After luteinization, luteinized granulosa cells are called luteal cells and produce high amounts of progesterone. Progesterone stimulates blood vessel growth and nutrient secretion in the endometrium of the uterus to support the implantation of the embryo.

FSH stimulates proliferation of granulosa cells; however, after the LH surge, granulosa cells stop dividing and exit the cell cycle. Luteal cells are found arrested predominantly at the G_0/G_1 phase of the cell cycle. Cessation of cell proliferation during luteinization is associated with a progressive loss of positive cell-cycle regulators, including cyclins and *Cdk2*, and with increased expression of the *Cdk* inhibitors *p21^{cip1}* and *p27^{kip}*. In addition, luteinizing granulosa cells express factors that stimulate the development of an extensive web of blood vessels, which provide not only the substrates for progesterone synthesis but also a mechanism to transfer of the high amounts of progesterone produced by luteal cells to the systemic circulation. One such factor is VEGF, which is expressed in the granulosa compartment only at the preovulatory stage. After ovulation, luteal cells continue expressing VEGF. The block of VEGF before ovulation inhibits luteal angiogenesis (Stocco et al., 2007).

Aging

Aging has a significant effect on ovarian function and, in particular, on granulosa cells. With age, granulosa cells show an increase in oxidative stress, leading to the formation of reactive oxygen species (ROS), which can damage lipids, proteins, and DNA. The formation of ROS could be triggered by a decline in superoxide dismutase, which neutralizes ROS, observed in aging granulosa cells. Additionally, the expression of glutathione S-transferase theta 1 (GSTT1) is increased in the granulosa cells of older women, an indication of increased oxidative stress. In studies of in vitro fertilization patients, women with granulosa cells that expressed high levels of GSTT1 have a significantly lower oocyte developmental capacity and lower cumulus-oocyte complex maturity compared to patients with low GSTT1. The increase in ROS correlates with FSH receptor downregulation and dysregulation of FSH action including disrupted steroidogenesis. This effect may explain the poor response to FSH observed in older women.

In addition to oxidative stress, reactive carbonyl species (RCS) are also thought to contribute to the functional decline of granulosa cells with aging. RCS are derivatives of metabolic processes, such as glycolysis, and they promote the formation of advanced glycation end products (AGEs). AGE-modified proteins and receptor for advanced glycation end products (RAGE) have been detected in granulosa cells. Activation of RAGE by AGE-modified proteins results in the generation of ROS and the expression of proinflammatory genes. Studies of granulosa cells retrieved from in vitro fertilization patients revealed that older women expressed significantly more RAGE than younger women. Thus, RCS accumulation during aging could lead to granulosa cell dysfunction by increasing ROS and inflammatory pathways (Avila et al., 2016).

Tumors

Granulosa cell tumors (GCT) are the most common type of ovarian sex cord tumors, which represent approximately 8% of ovarian cancers. GCTs are classified into juvenile GCT or adult GCT, each having unique histology and genetic mutations. Juvenile GCTs are rare and make up only 5% of all GCTs. Approximately 30% of these tumors have activating mutations in the *Gsp* oncogene, which encodes the α subunit of Gs. Also, roughly 60% of GCT tumors contain activating mutations of AKT. In contrast, more than 97% of adult GCTs contain a single missense mutation in the *FOXL2* gene, *FOXL2* C134W. Interestingly, although the biological action of *FOXL2* in many aspects of ovarian physiology is well understood, the mechanisms by which *FOXL2* C134W results in tumorigenesis have not been established.

Both juvenile and adult GCTs produce high levels of estrogens that can become symptomatic. Hyperestrogenism can cause precocious puberty in children and irregular bleeding in reproductive-age or postmenopausal women. These symptoms often lead to the GCT diagnosis. The high levels of estrogen can also result in endometrial hyperplasia or carcinoma. Granulosa cell markers, such as AMH and inhibin, are used in diagnosis and monitoring of GCTs. Overall, the majority of GCTs are diagnosed at an early stage and have a good prognosis after surgical intervention.

Conclusion

The granulosa cells are central for female reproduction. These cells establish a very close relationship with the female gamete even before oögonia differentiation during embryogenesis. This relationship continues for months or years and during the maturation of primary and secondary oocytes. After ovulation, cumulus granulosa cells escort the oocyte to the oviduct, whereas the mural granulosa cells that remain in the ovary are transformed into luteal cells. Luteal cells are necessary for implantation and early development of the zygote. The understanding of the intricate mechanisms, pathway activation, and gene expression in the granulosa cells at each of these steps is still evolving.

Theca Cells

Introduction

Definition of the Theca Cell Layer

Theca is a Latin word for a casing or sheath. The theca cell layer of the ovarian follicle is an envelope of connective tissue surrounding the granulosa cells. The inner-most layer that is closest to the granulosa cells is called the theca interna; the outer-most layer is called the theca externa. The theca interna contains the endocrine cells that produce the steroid hormones. The theca externa is a connective tissue layer derived from fibroblast-like cells that produce extracellular matrix factors, such as collagen. The theca interna and externa also contain a rich supply of blood vessels called the vascular tissue that brings nutrients, oxygen, and immune cells to the growing follicles. Thus, the theca layer of ovarian follicles is critical not only for maintaining the structure of the follicle but also for delivering nutrients to the granulosa cells and oocyte that reside in a non-vascular environment within the follicle (Young and McNeilly, 2010) (Fig. 1).

Endocrine Functions of Theca Cells

The cells within the theca that produce and secrete steroid hormones are called theca endocrine cells. The secreted steroid hormones act as messengers that travel through the blood stream to alter the function of distant tissues and thereby coordinate the development and metabolic homeostasis of the body. Studies in the 1970s documented that theca cells in growing follicles produce steroid hormones called androgens, primarily androstenedione, testosterone, and dihydrotestosterone. Moreover, it was discovered that androgens produced by the theca were then converted to another steroid hormone, estradiol, by the aromatase enzyme in granulosa cells (Young and McNeilly, 2010).

Theca endocrine cells produce androgens in response to the pituitary hormone called luteinizing hormone (LH). Studies in the 1970s documented that LH stimulated theca cell steroidogenesis by binding to a molecule on the surface of the theca cells called the LH receptor. By binding to this receptor, LH triggers a cascade of intracellular signaling pathways leading to the production of androgens. Furthermore, LH receptors were shown to be present in theca endocrine cells of small preantral, antral, and preovulatory

Fig. 1 Theca cells in growing follicles express collagen IV (COLIV) an extracellular matrix protein that provides structural integrity. COLIV is also present in the ovarian stroma but is not present in granulosa cells. Theca cells are recruited to the growing follicles and are functionally regulated by the Hedgehog (HH) signaling pathway. Specifically, GDF9 secreted from the oocyte induces the expression of IHH and DHH in granulosa cells. These ligands then bind to and activate their receptors (PATCHED1 and PATCHED2) in theca cells. This activation prevents PATCHED1/2 inhibition of another theca cell membrane signaling molecule SMOOTHENED. Activated Smoothened then increases the transcription of specific genes via the nuclear transcription factors, Gli1 and Gli2. Two genes of particular interest are alpha smooth muscle actin (*Acta2*) that is a marker of stromal fibroblast and perivascular cells and the steroidogenic gene, cytochrome P450 17a1 (*Cyp17a1*) that is critical for androgen biosynthesis. Adapted from Richards, J.S., Ren, Y.A., Canderlaria, N., Adams, J.E., Rajkovic, A. (2017). Ovarian follicular theca cell recruitment, differentiation and impact on fertility. *Endocrine Reviews* (advanced publication). <https://doi.org/10.1210/er.2017-00164>.

follicles but not to primordial follicles. The LH receptor was only detected in granulosa cells of the preovulatory follicles whereas receptors for follicle stimulating hormone (FSH) were only expressed in granulosa cells. Collectively, these seminal studies led to the two-cell, two gonadotropin theory of steroidogenesis; namely that theca endocrine cells bind LH and produce androgens whereas the granulosa cells bind FSH and produce estradiol (Richards, 1994). Thus, the theca endocrine cells are homologous to the LH responsive, androgen-producing Leydig cells of the testis.

In the ovary, the theca and granulosa endocrine cells control the levels of steroids not only within the follicle but also in the peripheral blood to act on cells in the hypothalamus and pituitary to control the production and release of LH and FSH that control follicle growth and ovulation. Estradiol, in particular, is essential for stimulating the mid-cycle surge of LH that stimulates ovulation (Young and McNeilly, 2010).

Theca Cell Derivation

The Role of GDF9

Recent studies have shown that theca cells within the theca layer of growing follicles are derived from two different sources in the embryo (Liu et al., 2015). One source is comprised of cells migrating into the embryonic ovary from a region called the mesonephros that eventually gives rise to the kidney and adrenal as well as contributing precursor cells to the gonads. The other source is cells present in the medullary region of the embryonic ovary itself. These fetal progenitor cells differentiate into what are known as adult theca cells. Those from the mesonephros become the steroidogenic androgen-producing cells; those from the ovary become theca fibroblasts, perivascular smooth muscle cells, and interstitial ovarian tissue.

A major discovery about what factors regulate the formation of the theca layer came in 1996 when Dong et al. (1996) reported that ovarian function was disrupted in transgenic mutant mice in which a factor, growth differentiation factor 9 (GDF9) was genetically deleted. Because GDF9 is produced by the oocyte of growing follicles, these observations provided the first evidence that the oocyte was controlling the recruitment of theca cells to the developing follicle. Hence, theca cells in the *Gdf9* null mice fail to organize around the granulosa cells to form a follicle, and as a consequence, ovarian follicular growth is arrested at the primary, small pre-antral stage (Dong et al., 1996). Arrested follicular development was also observed in sheep and humans harboring mutations in the *GDF9* gene (Young and McNeilly, 2010). These observations provided the first evidence that a factor from the oocyte was regulating the function and formation of the theca cell layer (Dong et al., 1996). Recent studies have shown that the effects of GDF9 on theca cell organization and function are mediated, at least in part, by the induction and activation of hedgehog (HH) signaling pathways (Liu et al., 2015) (Fig. 1).

The Role of Hedgehog Signaling

The HH signaling pathway has many components and acts to control local cell–cell interactions and patterning. The extracellular ligands called Desert hedgehog (DHH), Indian hedgehog (IHH) are expressed selectively in granulosa cells of growing follicles. These ligands bind the HH cell surface transmembrane receptors PATCHED 1 (PTCH1) and PTCH2 present in theca cells as well as in interstitial/fibroblast and/or perivascular cells within the theca layer. This paracrine activation of PTCH1/2 releases PTCH1/2 inhibition of Smoothened (SMO), a G protein coupled receptor, leading to down-stream induction and/or activation of the transcription factors GLI1, 2, or 3. GLI1 originally isolated from glioblastoma cells and is known to regulate many genes and in some contexts can be an oncogene. Based on elegant cell lineage analyses, GLI1 is now a known marker of theca precursor cells that differentiate into the theca steroidogenic cells in the adult ovary (Liu et al., 2015). Activation of SMO also leads to the induction of inhibitory factors, *Ptch2* and hedgehog interacting protein, *Hhip*, providing autocrine negative regulatory loops within the follicle. HH signaling is thus tightly controlled at a local level within the follicle.

Interestingly, GLI1, 2, and 3 are also markers of Leydig precursor cells in the testis (DeFalco et al., 2011) indicating that there are parallels between the neonatal and embryonic development of the ovary and testis, respectively, with the main differences being related to when these factors and pathways are activated in the developing gonads. For example, Morohashi and colleagues identified a fetal Leydig cell specific enhancer that drives expression of the transcription factor SF-1 in the fetal testis. When female mice expressing the same EGFP-tagged-fetal Leydig enhancer were analyzed, EGFP positive cells were identified not in the fetal ovary but rather in the postnatal ovary that represented theca cells and interstitial cells, some of which were positive for 3-beta hydroxysteroid dehydrogenase/isomerase (3βHSD) and were steroidogenic whereas other cells were not (Shima et al., 2011). These results support observations that there are steroidogenic and non-steroidogenic cells within the theca layer that likely derive from two different progenitor cell types in the embryonic and neonatal ovaries (Liu et al., 2015). Furthermore, overexpression of the HH pathway in the fetal ovary of *Sf-1/Cre; Smo^{YFP}* mice leads to the appearance of fetal Leydig cells, premature increases in androgen production and female pseudohermaphroditism in the female mutant mice (Barsoum et al., 2009). A similar phenotype was not induced in the *Amhr2-Cre; Smo* mutant mice (Ren et al., 2012) indicating that *Amhr2* is not as strongly expressed in steroidogenic precursor theca cells but rather is a more potent driver theca precursor cells that give rise to components of the stroma, including fibroblasts and perivascular smooth muscle cells. Because *Amhr2* is expressed in the embryonic (E17.5) gonad and in some cells of the theca and stroma of the adult ovary, it is also possible that the effects of over-expressing SMO are developmentally stage dependent and precursor cell specific.

Fig. 2 Theca cell production of androgens, primarily testosterone, is critical of normal follicular development. Androgen biosynthesis is increased not only by the HH signaling pathway but also by luteinizing hormone (LH), insulin (INS), insulin-like growth factor 1 (IGF1), and insulin like 3 signaling pathways. Conversely, members of the BMP/TGF β family can antagonize theca cell androgen biosynthesis. Androgens impact follicular development by binding to androgen receptors (AR) present in granulosa cells, theca cells, and stromal cells. In granulosa cells androgens regulate expression of the FSH receptor (*Fshr*) and connective tissue growth factor (*Ctgf*) and in the presence of FSH regulate the expression of aromatase (*Cyp19a1*) and the LH receptor (*Lhcgr*), markers of preovulatory follicles. The genes regulated by androgens and AR in theca cells and stromal cells remain to be identified. HH signaling also controls expression of *Acta2* in theca fibroblasts and endothelial cells. Adapted from Richards, J.S., Ren, Y.A., Canderlaria, N., Adams, J.E., Rajkovic, A. (2017). Ovarian follicular theca cell recruitment, differentiation and impact on fertility. *Endocrine Reviews* (advanced publication). <https://doi.org/10.1210/er.2017-00164>.

Mouse models in which SMO is over-expressed have revealed key functions of the HH pathway, particularly in regulating genes within the steroidogenic pathway including *Cyp11a1* and *Cyp17a1*. CYP11A1 controls the first step in steroidogenesis, namely the conversion of cholesterol to pregnenolone that is eventually, by a series of enzymes including CYP17A1, converted to testosterone. Over-activation of SMO also leads to the absence of perivascular smooth muscle cells in the theca of growing follicles. The lack of α SMA is evident as early as postnatal day 8, continues throughout follicle development and is associated with defective ovulation (Ren et al., 2009). Thus, over-activation of SMO in the embryonic ovary appears to enhance the functions of theca endocrine precursor cells but suppresses functions of fibroblasts and vascular smooth muscle cells (Fig. 2).

Recent studies also show that the oocyte-derived factor GDF9 regulates the expression of DHH and IHH in granulosa cells, thereby providing a potential explanation for why loss of GDF9 disrupts theca cell recruitment and proliferation, steroidogenesis, and hence follicle growth (Liu et al., 2015). As proof of principle, genetic disruption of the *Dhh* and *Ihh* in mice in ovarian cells markedly reduces expression of steroidogenic enzymes, including CYP17A1, and levels of testosterone and progesterone. Loss of DHH and IHH also reduces α -SMA/ACTA2 expression and impairs follicular growth (Liu et al., 2015). Thus, the HH signaling pathways impacts many aspects of the cell function and follicular development.

Theca Endocrine Cell Differentiation and Function

The nuclear receptor SF-1 or NR5A1 regulates many steroidogenic genes in the gonads and adrenal. Mice null for *Sf-1* revealed that SF1 has far reaching functions in endocrine cells: the mice are infertile and lack gonads, pituitary gonadotrophs, as well as adrenal glands (Young and McNeilly, 2010). Based on deletion studies, DHH and IHH are implicated in regulating the differentiation and steroidogenic capacity of endocrine cells including adrenal, theca, and Leydig cells, in part, by regulating the expression of *Sf-1*/*Nr5a1* and steroidogenic enzymes *Cyp11a1* (Liu et al., 2015). Over-expression of HH signaling by *Amhr2-Cre* driven expression

of SMO leads to abnormal expression of *Shh*, *Star*, and *Cyp21a1* in what appear to be adrenal-like cells in the day 2 postnatal ovary but does not alter steroidogenesis in ovaries of adult mice (Ren et al., 2012). By contrast, activation of HH signaling with *Sf-1/Cre*; *Smo^{YFP}* leads to the induction of Leydig cells in the fetal ovary and female mice that exhibit pseudohermaphroditism (Barsoum et al., 2009). These results indicate that activation of HH signaling in theca cells impacts steroidogenesis in a stage, cell, and context specific manner.

Recent studies have further shown that theca “stem” cells can be isolated from neonatal mouse ovaries and stimulated to differentiate in culture or when transplanted to a recipient host ovary in vivo (Honda et al., 2007). Specifically, theca stem cells cultured in serum free media expressed theca cell markers, *Ptch1* and *Gli3* but were morphologically undifferentiated, and non-steroidogenic. When serum was added to the culture media, small lipid droplets accumulated and LH receptor (*Lhcgr*) mRNA was noted. However, the most dramatic changes were observed when theca stem cells were cultured in granulosa cell conditioned media or were co-culture with granulosa cells. Under these conditions, the theca stem cells acquired a steroidogenic morphology (lipid droplets and smooth endoplasmic reticulum), increased expression of *Lhcgr* and *Gli2*, and elevated androstenedione production. When EGFP-tagged theca stem cells were transplanted to an ovary of a recipient mouse in vivo, EGFP+ cells were found in the theca layer of growing follicles indicating that they had been recruited to growing follicles. It is likely that these theca stem cells differentiate not only in response to IHH/DHH but also to LH and other granulosa cell-derived factors, including insulin like growth factor, stem cell factor (kit-ligand), epidermal growth factors, as well as by intrafollicular regulatory factors including inhibins, activins, and BMPs (Glister et al., 2013; Young and McNeilly, 2010) (Fig. 2).

Other Regulators of Theca Cell Function

Insulin-like 3 (INSL3) is expressed at high levels in testicular Leydig cells and is critical for testicular descent in males. INSL3 is also expressed in and impacts theca cell functions in the ovary (Glister et al., 2013). Specifically, INSL3 and its receptor (relaxin/insulin-like family peptide receptor 2; RXFP2) appear to modulate LH-mediated androgen biosynthesis. INSL3 null female mice exhibit increased apoptosis and luteal regression whereas over-expression of INSL3 in fetal and neonatal INSL3 null mice leads to ovarian descent within the peritoneum but does not impair ovarian function. The effects of LH and INSL3 are antagonized dramatically by activin and BMPs (BMP2, 4, 6, 7) that are produced by granulosa cells and/or oocytes (Glister et al., 2013; Young and McNeilly, 2010). Inhibin B blocks the inhibitory effects of activin and BMPs, thereby creating a local regulatory network within growing follicles (Young and McNeilly, 2010). BMPs are also blocked by the BMP antagonist gremlin that is induced by oocyte-derived GDF9 but markedly reduced by loss of *Smad1/5* or *Bmpr1* in granulosa cells (Edson et al., 2010), providing another local regulatory network, especially in small follicles and within the cumulus cell–oocyte complex of larger follicles.

Circadian rhythms impact reproduction as evidenced by more than 4000 publications listed in PubMed. At the cellular level circadian rhythms are controlled by the molecular clock, a feedback loop of transcription factors that impacts the cyclic expression of target genes in peripheral tissues. Two of these factors, CLOCK (circadian locomotor output cycle kaput) and BMAL1 (brain and muscle ARNT-like protein 1), impact reproductive function not only at the hypothalamic-pituitary level but also in the ovary (Mereness et al., 2015). Theca cell specific disruption of *Bmal1* gene in mice expressing *Cyp17-Cre* leads to changes in the circadian expression of the LH receptor (*Lhcgr*), reduced sensitivity of the ovaries to LH and subfertility, suggesting that BMAL1 acts as a pacemaker of LH sensitivity (Mereness et al., 2015). Disruption of *Bmal1* in mice expressing *Sf1-Cre* blocks expression of *Star*, progesterone production in corpora lutea and implantation, indicating that BMAL1 also impacts steroidogenesis.

Androgens produced by theca cells exert paracrine functions within the ovary by binding and activating the androgen nuclear receptor (AR/NR3C4) that is present in multiple cell types within the ovary (Lenie and Smitz, 2009) including granulosa cells, theca cells, and stromal cells. Targeted disruption of the androgen receptor (*AR*; *Nr3c4*) in granulosa cells impairs follicular development (Lebbe and Woodruff, 2013). Androgens are made in small follicles and regulate the expression of FSH receptor (*Fshr*) leading to early follicle growth and eventually, with FSH, they promote expression of *Cyp19a1* (aromatase) and *Lhcgr* in granulosa cells of antral follicles (Young and McNeilly, 2010). Moreover, androgens act in granulosa cells via AR canonical and non-canonical pathways to promote cell survival (Sen et al., 2014). However, the role of androgens in other cell types (theca, stromal, fibroblastic, immune) within the ovary is less well characterized but appears to impact not only normal processes in the ovary but also the ovarian phenotype of women with PCOS (see below).

Structural and Matrix-Related Functions of Theca Cells

The theca layer of growing follicles provides a structural framework that is largely composed extracellular matrix factors, including different types of collagen, vimentin, vascular cell adhesion molecule 1, laminin, fibronectin, proteoglycans, tenascin C, and fibrillins. Although the matrix appears highly structured, it is not static. Rather the extracellular matrix within the theca of growing follicles undergoes dynamic changes during follicular development (Irving-Rodgers et al., 2010) and contributes to follicular function. Pioneering studies of Woodruff and Shea have shown that the rigidity of the extracellular matrix impacts not only follicle growth but also its steroidogenic potential (Woodruff and Shea, 2011). Using a tissue-engineered artificial matrix made of alginate, they have also documented that follicles grown in this extracellular milieu produce live, fertile offspring. Moreover small follicles cultured in

the presence of stroma, containing theca cells and macrophages, grow better and survive longer than follicles cultured in the absence of stroma indicating that the dependence of follicles on the ovarian stroma is stage dependent (Tingen et al., 2011).

Based on these studies, it is not surprising that the composition of the theca matrix undergoes constant remodeling and that expression of factors within the theca and that impact the matrix change during follicle growth and apoptosis (Hatzirodos et al., 2014a,b). However, microarray analyses have revealed that the gene expression patterns in bovine theca cells exhibit fewer changes during follicular growth and atresia than the gene expression patterns in bovine granulosa cells (Hatzirodos et al., 2014a,b). In particular, the microarray analyses reveal that theca derived from small and large bovine follicles express not only collagen 1 (COL1A1) but also many other types of collagen. Also of note, theca of small follicles express neuronal cell adhesion molecule (NCAM1) and intercellular adhesion molecule (ICAM1) that likely impact vascular cells; theca of large follicles also express vascular cell adhesion molecule (VCAM1) that helps recruit immune cells, is a marker of theca cell lineage in the embryonic mouse gonad (DeFalco et al., 2011), and is a potential androgen target gene (Death et al., 2004; Solano et al., 2011). Connective tissue growth factor (CTGF) that is an androgen target gene in murine granulosa cells is also expressed in bovine theca (Hatzirodos et al., 2014a). Although marked changes in gene expression patterns were not noted in bovine theca cells from small and large follicles, the tight junction protein Claudin11 was the most highly up-regulated gene in theca of large follicles (Hatzirodos et al., 2014a). The function of CLDN11 in theca cells is not known but may impact vascular permeability; it may also be an androgen target gene.

Bovine theca cells of small follicles undergoing atresia do not exhibit increased expression of genes or factors mediating apoptosis (Hatzirodos et al., 2014b), such as cleaved-caspase 3, BMP2, and FOXO1 as is observed in granulosa cells of mouse and presumably other species. Rather, the theca exhibited changes in genes related to cell cycle arrest and DNA replication (Hatzirodos et al., 2014b). In addition, the expression of cytokines, including interleukin IL6 and a macrophage related protein, glycoprotein non-metastatic melanoma protein B/osteostatin (GPNMB/OA) were increased (Hatzirodos et al., 2014b).

Vascular and Immune Cells in the Theca

The vascular network in the theca layer is essential for providing nutrients to the theca cells as well as to the avascular granulosa cells, cumulus cells, and oocyte. Although critical, little is known about what regulates the vascular tissue in the theca during follicular growth and what factors exclude vascular invasion of the granulosa cell layer until after ovulation. However, vascular endothelial growth factor (VEGF) is expressed in granulosa cells and is one important factor (Young and McNeilly, 2010). Targeted disruption of VEGF in granulosa cells or over-expression of an anti-angiogenic splice variant of VEGF leads to profound changes in follicular development and reduced fertility (Sargent et al., 2015). Based on bovine theca microarrays there appear to be only minor changes in vascular markers in theca of small and large follicles suggesting that the maintenance of vascular tissue is relatively stable and critical during follicle growth. However, markers of vascular cells are clearly evident in the theca (Hatzirodos et al., 2014a). As noted above, VCAM1 is higher in theca of large follicles (Hatzirodos et al., 2014a), perhaps due to increased androgen levels. Immune cell markers are also present, including members of the complement pathway (Hatzirodos et al., 2014a). Furthermore, the number of immune cells, namely macrophages, associated with growing follicles increases during the pre-pubertal period in mice and these macrophages are associated not only with apoptotic follicles but also with healthy secondary follicles (Tingen et al., 2011). Clearly, additional studies are needed to fully characterize what controls the vascular tissue and immune cell functions in the theca of growing follicles. It is highly likely that there are specific molecular markers that characterize the vascular tissue and immune cells associated with follicles at defined stages of growth (Nolan Daniel et al., 2013).

By contrast to events in small growing follicles, marked changes occur in gene expression profiles in the theca following LH induction of ovulation (Christenson et al., 2013). In addition, there are major changes in the follicular vasculature following ovulation when vessels rapidly invade the granulosa cell layer and contribute to the formation of the corpus luteum (Richards et al., 2015). Targeted disruption of the MAP kinases (MAPK1/3; ERK1/2) in granulosa cells prevents not only ovulation but also the invasion of vascular cells into the granulosa cell layer. These observations provide evidence that the MAPK pathway is essential for LH induction of ovulation and that vascular invasion does not occur in the absence of ovulation. Additionally, targeted disruption of genes encoding the transcription factors, CCAAT enhancer binding proteins alpha and beta (*Cebpa* and *Cebpb*) in granulosa cells also blocks ovulation and vascular invasion (Richards et al., 2015). Gene expression profiles in granulosa cells of these mice document that specific genes other than, or in addition to VEGF, are markedly increased during ovulation and likely contribute to the vascular invasion of the granulosa cell compartment. Immune cells are essential for this process, based on evidence that depletion of immune cells either by clodronate treatment (Turner et al., 2011) or diphtheria toxin mediated immune cell disruption (Care et al., 2013), prior to ovulation blocks corpus luteum formation. The recruitment of immune cells is dependent on follicular expression of cytokines and chemokines, including IL6 and CCL20 (Adams et al., 2016; Al-Alem et al., 2015), and expression of these factors appears to depend on LH, androgens, and IL6 (Adams et al., 1991).

Theca Cell Functions in Disease

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) is the leading cause of anovulatory infertility in women in their reproductive years (Diamanti-Kandarakis and Dunaif, 2012; Rosenfield and Ehrmann, 2016). Patients with PCOS exhibit excess androgens (hyperandrogenemia),

the defining characteristic of this endocrine disorder (Diamanti-Kandarakis and Dunaif, 2012; Rosenfield and Ehrmann, 2016). The underlying causes of excess androgen appear to be multi-faceted but elevated theca production of androgens is considered a key event in determining the PCOS phenotype and theca cells derived from follicles of PCOS patients exhibit elevated, intrinsic androgen production and secrete higher levels of DHEA and 17OH progesterone in response to LH compared to theca cells of normal patients. Many other genes are also differentially expressed in theca of PCOS compared to non-PCOS patients. A genome-wide screen identified an DENND1A isoform variant V2 that, when over-expressed in normal theca cells in culture led to elevated androgen production and responses to LH (McAllister et al., 2014). Moreover, when this isoform was expressed in mice, it recapitulated a PCOS ovarian phenotype in vivo (McAllister et al., 2014).

Elevated androgens in PCOS follicles alter not only the functions of theca and granulosa cell obtained from patients undergoing IVF but also may impact premature arrest follicle growth that leads to the anovulatory phenotype of PCOS (Rosenfield and Ehrmann, 2016). The mechanisms by which elevated androgens lead to follicle arrest in PCOS are not entirely clear but may be related to an increase in AR mediated expression of FSHR and increased responsiveness of small growing follicles to FSH leading to premature differentiation and luteinization. Alternatively, elevated AMH in the arrested follicles appears to impact and reduce early follicle growth by antagonizing FSH action.

Importantly, the expression of AR is not restricted to granulosa cells. Rather, AR is present in multiple cells types within the ovary (theca, fibroblast, stroma, immune, and endothelial cells), can act on these cells, and contribute to the multifaceted effects of androgens on the PCOS ovarian phenotype. For example, the ovarian stroma of PCOS patients is characterized by increased fibroblast proliferation, collagen deposition, and thus inherent rigidity (Lebbe and Woodruff, 2013). Increased rigidity provides another explanation for follicle growth arrest in PCOS (Lebbe and Woodruff, 2013).

Androgens can also stimulate the expression of VEGFA in PCOS ovaries that impacts vascular cell growth (Young and McNeilly, 2010). As mentioned above, VEGFA and its proangiogenic and anti-angiogenic splice variants have been identified in the ovary. Targeted disruption of VEGF in granulosa cells in mice leads to impaired follicular development and expression of specific genes. An anti-angiogenic splice variant of VEGF is expressed in theca cells of marmosets. Over-expression of this anti-angiogenic splice variant in the ovary of mice impaired follicular development leading to increased follicular atresia (Qiu et al., 2012).

In addition, there appears to be a functional link between elevated androgens in PCOS patients and inflammatory conditions both at the systemic level, within the stroma and granulosa cells of ovulatory follicles of PCOS patients undergoing IVF (Schmidt et al., 2014), especially those that are obese (Adams et al., 2016). Specifically, the expression of many cytokines and chemokines, such as IL6, IL7, CCL20, are elevated in granulosa cells isolated from PCOS patients compared to non-PCOS patients undergoing IVF (Adams et al., 2016; Al-Alem et al., 2015). These observations document that there is an enhanced local, intra-ovarian inflammatory response associated with a PCOS patients, many of whom are obese (Adams et al., 2016). The elevated levels of cytokines appear to be associated, in part, with the enhanced local recruitment of CD45⁺ immune cells because the cytokine profile in follicular fluid differs from that observed in peripheral serum (Adams et al., 2016). Whether theca-derived androgens directly alter immune cells is not yet clear. However, that androgen receptors are present in immune cells and can exert specific functions may explain, in part, the proinflammatory condition of PCOS.

Animal models of PCOS have been established in mice, rats, primates, and sheep. These models are based mainly on elevating androgens prenatally or post-natally and mimic many but not all aspects of the human condition. Importantly, these studies indicate that androgens may exert epigenetic effects leading to metabolic syndrome and anovulation associated with PCOS (Rosenfield and Ehrmann, 2016; Walters et al., 2012).

Premature Ovarian Failure

Although most causes of POF remain idiopathic and unknown, it is clear that disruption of theca cell derivation or function during embryonic and post-natal periods can lead to abnormal follicle formation and growth. As mentioned above, depletion of the oocyte derived factor GDF9 in mice prevents the organization of the theca cell layer leading to follicle growth arrest, POF, and infertility (Dong et al., 1996). Mutations in the human *GDF9* gene have been reported and are associated with POF (Laissue et al., 2008), providing evidence that GDF9 is critical for ovarian function in women. One would predict that disruption or mutation of factors regulating GDF9 expression, levels, or activity would also lead to POF. Of relevance, newborn ovary homeobox (NOBOX) protein that is expressed in the oocyte, and if deleted, leads to impaired expression of *GDF9* and follicle growth arrest (Rajkovic et al., 2004). Moreover, the *GDF9* gene is a direct target of NOBOX. Recent studies have further shown that some women (6.2% of a cohort analyzed) have mutations in the *NOBOX* gene and these women present POF (Bouilly et al., 2014). Significantly, although disruption of *Ihh* and *Dhh* or over-expression of SMO in ovarian cells in mice is associated with abnormal theca cell development and function, mutations in the HH signaling pathway genes have not yet been linked to POF in women.

Introduction

In his book, “*Exercitationes de generatione animalium*,” first published in 1651, the renowned physician scientist William Harvey stated that “*ex ovo omnia*,” or all comes from the oocyte. This statement aptly encompasses the concept that the foundation for embryo development (embryogenesis) lies in oocyte development (oogenesis). The oocyte is one of the largest, rarest, and most vital cells in the human body—capable of giving rise to an entirely new generation. During its growth phase within the ovarian follicle, the oocyte generates maternal products (i.e., organelles, RNAs, and proteins), which are essential for supporting subsequent fertilization and early embryo development (Figs. 1 and 2A). There is a corresponding volumetric expansion due to these accumulated products, and human and mouse oocytes increase in volume > 100-fold and 200-fold, respectively, during their growth phase. In this article, we consider the mammalian oocyte—from its structure to critical biological processes in its development and to factors that influence its quality.

Cellular Architecture

The bulk cytoplasm or volume of the embryo originates from the oocyte rather than from the sperm at the time of fertilization. Therefore, the maternal products that accumulate with the oocyte during its growth phase endow the embryo with materials essential for early development. Here, we describe the key cellular structures within the mammalian oocyte and highlight unique features that make it distinct from other cells.

Germinal Vesicle (Oocyte Nucleus)

The germinal vesicle (GV) is the nucleus of the oocyte (Figs. 1B and 2B). The GV is large and spherical and contains chromatin (DNA) and the nucleolus (Figs. 1B and 2B). The oocyte chromatin is located throughout the GV, and its exact configuration

Fig. 1 Histology of a prepubertal mouse ovary showing oocytes within the context of the follicle. (A) A scan of a histological section of a prepubertal mouse ovary (postnatal day 10) stained with hematoxylin and eosin that stains cell nuclei and cytoplasm, respectively. Oocytes within follicles in early stages of development are visible throughout the ovary. The region outlined by the gray box is further magnified in (B). All oocytes within the ovary, regardless of follicle stage, are arrested in prophase of meiosis I and have an intact, visible nucleus that contains DNA. The oocyte nucleus is called the germinal vesicle (GV) and is highlighted by the arrowhead. Scale bars are 100 μ m.

Fig. 2 Histology of an adult mouse ovary and a transmitted light image of a fully grown mouse oocyte. (A) A scan of a histological section of an adult mouse ovary stained with hematoxylin and eosin. Oocytes within follicles at all stages of development are visible, including one in a large antral follicle (*black arrow*). A transmitted light image of a fully grown oocyte that was isolated from a large antral follicle is shown in (B). The oocyte nucleus or germinal vesicle (GV) is outlined with a *dotted white line*, and the nucleolus is visible within it. The oocyte plasma membrane (PM) is highlighted by the *white arrow*, and the zona pellucida (ZP)—or glycoprotein matrix—that surrounds the oocyte is highlighted by the *black arrow*. The scale bar is 100 μm (A) and 25 μm in (B).

depends on the transcriptional activity of the oocyte as described further in the section “**Meiotic Competence**” (Fig. 1B). All oocytes within the ovary are arrested in the dictyate stage of prophase of meiosis I (MI), and this meiotic stage is characterized by the presence of an intact GV, which can be identified morphologically by histology and light microscopy (Figs. 1B and 2B). Oocytes maintain this meiotic arrest throughout oogenesis as they grow in size and accumulate the necessary maternal products to support the completion of meiosis, fertilization, and early preimplantation development. The prophase I arrest is maintained by high intra-oocyte cyclic adenosine monophosphate (cAMP) levels (Jaffe and Egbert, 2017). In the oocyte, cAMP is regulated by the opposing activities of adenylyl cyclase 3 (AC3) and the oocyte-specific phosphodiesterase (PDE3A). AC3 produces cAMP, whereas PDE3A destroys it. In the granulosa cells (mural and cumulus), the NPR2 guanylyl cyclase produces cyclic guanosine monophosphate (cGMP) that diffuses into the oocyte and inhibits PDE3A, thus keeping oocyte cAMP levels high and maintaining meiotic arrest (Jaffe and Egbert, 2017).

Within the GV is the nucleolus, an electron-dense organelle whose prime function is ribosome biogenesis (Figs. 2B, 3, and 4A). Ribosomes are small organelles responsible for protein synthesis. The size of the nucleolus is related to the ribosomal requirements of the cells in which they are found. Because the oocyte has high metabolic demands, it has a very prominent nucleolus that is visible by light microscopy, and some oocytes have multiple nucleoli (Fig. 2B).

The GV is lined by a nuclear envelope, which is supported by the nuclear lamina—a proteinaceous layer composed of lamin proteins situated between the chromatin and inner nuclear membrane (Figs. 2B, 3, and 4B). The nuclear envelope is punctuated by pores that provide the means for the regulated exchange of material between the nucleus and cytoplasm (Figs. 3 and 4B). For example, ribosomal components and newly transcribed RNAs must be transported to the cytoplasm for protein production to occur.

Cytoplasm and Organelles

The cytoplasm of the oocyte contains the many organelles vital to its growth. Early in development, when oocytes are within germ-line cysts or primordial follicles, they contain a large distinctive organelle aggregate called the Balbiani body that consists of mitochondria, endoplasmic reticulum (ER), and Golgi elements (Pepling et al., 2007). However, the Balbiani body disperses later during oocyte growth, and organelles have a broader cytoplasmic distribution. Mitochondria are the energy-producing organelles of the oocyte. Mitochondria increase dramatically in number from a small founder population by fusion or fission during oogenesis. This accumulation is necessary to endow the early embryo with mitochondria, since their biogenesis ceases in the mature oocyte and does not resume until after fertilization (Babayev and Seli, 2015). Mitochondria in the oocyte have three distinct morphologies: those with typical cristae (or folds) seen in somatic cells, those with vacuoles between cristae, and those without cristae (Figs. 3 and 4C; Ruby et al., 1969). Mitochondria are usually in close proximity to the ER.

There are two types of ER in the oocyte. In general, the smooth ER aids in lipid synthesis and transport. In the maturing oocyte, the smooth ER near the oocyte cortex is also a main storage site for intracellular calcium stores, which are ultimately responsible for the rise in cytosolic calcium that occurs during fertilization (Figs. 3 and 4D; Machaty, 2016). The rough ER is distinct from the

Fig. 3 Schematic of the subcellular architecture of the mammalian oocyte. This schematic highlights the cell biology of the mammalian oocyte, and corresponding structures and organelles are shown at the ultrastructural level in Fig. 4.

smooth ER because it is punctuated with ribosomes and aids in the production and transport of proteins and other biomolecules (Figs. 3 and 4E). In oocytes, the ER is typically poorly developed or connected to neighboring mitochondria, perhaps to aid in protein transport (Ruby et al., 1969). In addition to being associated with the ER, ribosomes are also found on unique structures known as cytoplasmic lattices (CPLs) (Figs. 3 and 4F). CPLs are made of a fibrillar matrix composed of proteins and RNA and could possibly contain intermediate filaments, like keratin (Yurttas et al., 2008). A major protein component of CPLs is peptidylarginine deiminase 6 (Yurttas et al., 2008). As the oocyte grows, CPLs increase, while cytoplasmic ribosomes decrease, suggesting that CPLs function as storage structures for the maternal contribution of ribosomes and RNA to the early embryo.

The Golgi apparatus is composed of a stack of membranous compartments or cisternae and is the organelle responsible for the secretion and intracellular transport of proteins from the ER (Figs. 3 and 4G). The main clusters of Golgi complexes are near the nucleus and on the periphery of the cytoplasm. In the oocyte, the Golgi apparatus is also involved in the generation of other critical structures and organelles. For example, the Golgi apparatus modifies several secreted glycoproteins that form a thick glycoprotein matrix or extracellular coat called the zona pellucida (ZP) (Figs. 2B and 3, discussed further later). Vesicles of hypertrophied Golgi complexes also fuse and become multivesicular bodies (MVBs) or cortical granules (CGs) (Liu, 2011). MVBs are late-stage endosomes that have intraluminal vesicles contained within larger vesicles. MVBs can target their contents to lysosomes for degradation. In addition, when MVBs fuse with the plasma membrane, they release their internal vesicles, which are called exosomes. Exosomes are now recognized as a new form of intercellular communication as they can contain several types of molecules, including miRNAs, proteins, and lipids. MVBs are clearly prominent within the oocyte cytoplasm, and their exact biological function is an active area of research (Figs. 3 and 4H). Hypertrophied Golgi clusters also form CGs, which are specialized organelles that are essential for proper fertilization. CGs form a monolayer-to-multilayer sheath beneath the plasma membrane (Figs. 3 and 4D). In the mature egg, upon fertilization and under the influence of a rise in intracellular calcium levels, CGs exocytose their contents in what is known as the cortical reaction (Liu, 2011). The CGs contain a protease, ovastacin, which cleaves ZP proteins in such a manner that modifies the glycoprotein matrix and prevents multiple sperm from entering the egg (i.e., polyspermy). Zinc-containing granules, which may be CGs or a subset of CGs, release zinc at the time of fertilization, and this zinc release also modifies the ZP to prevent polyspermy (Que et al., 2017).

Microvilli, Transzonal Projections, and the Zona Pellucida

The oocyte plasma membrane is covered by microvilli or small actin-rich membrane protrusions (Figs. 3 and 4D). In the mature egg, the microvilli become asymmetrically distributed, and sperm-egg interactions take place predominantly or exclusively in the region of the egg surface that contains microvilli (Calarco, 1991). The oocyte plasma membrane is surrounded by the ZP (Figs. 2B and 3). At the peak of protein synthesis in the oocyte, 5% of all proteins are destined for ZP production. More than 95% of the ZP is

Fig. 4 Ultrastructure of key organelles in the growing mouse oocyte. Late primary and secondary follicles were isolated from mouse ovaries and fixed and processed for electron microscopy. Regions within the oocyte were imaged using a JEOL JEM-1400 transmission electron microscope. (A) The nucleolus is the circular electron-dense structure. The nucleolus is a tripartite structure composed of dense fibrillar centers (DFCs), granular center, and fibrillar centers (FCs). The DFCs and FCs are clear at this magnification. The *black arrow* highlights the nuclear envelope. (B) The nuclear envelope forms a boundary between the GV and the cytoplasm. The *white arrow* highlights one of the nuclear pores that punctuates the nuclear envelope. (C) Oocyte mitochondria have unique morphologies including those with typical cristae (*white arrow*), those with vacuoles in between cristae (*black arrow*), and those without cristae (*asterisks*). (D) A view of the oocyte cortex or outer edge shows the plasma membrane, which abuts the ZP and is punctuated by microvilli (*asterisks*). The smooth ER is highlighted by the *black arrow*, and vesicles containing electron-dense material (possibly cortical granules) are highlighted by the *white arrows*. (E) The rough ER is typically found near mitochondria and has a rough-appearing surface due to the presence of ribosomes (*black arrow*). (F) Cytoplasmic lattices are unique oocyte structures that are prevalent in the cytoplasm and involved in ribosome storage. The *black arrow* highlights this structure, which is further magnified in the inset. The black dot-like structures are individual ribosomes. (G) The Golgi apparatus is visible as a stack of several membrane-covered sacs called cisternae (*black arrow*). (H) Large aggregates of multivesicular bodies are found in the oocyte cytoplasm (*black arrow*). The nuclear envelope is highlighted by the *white arrow*. In all images, GV is the germinal vesicle, cyto is the cytoplasm, and the scale bars are 500 nm.

composed of three glycoproteins: ZP1, ZP2, and ZP3 (Wassarman and Litscher, 2013). The ZP physically separates the oocyte from adjacent granulosa cells. Transzonal projections (TZPs) are actin- and microtubule-rich structures that extend from granulosa cells, transverse the ZP at varying angles, and make contact with the oocyte (Plancha et al., 2005). TZPs allow bidirectional communication and passage of molecules to occur between the oocyte and its surrounding granulosa cells via gap junctions. Gap junctions are composed of a family of proteins called connexins. Connexin-37, for example, is expressed by the oocyte and is essential for proper follicle development as it bridges the oocyte to the surrounding somatic cells (Winterhager and Kidder, 2015). Of note, diverse factors and molecules have been observed within TZPs, including nutrients, small molecules (i.e., cGMP), and organelles. In addition to playing a vital role in cell growth and communication, the ZP also plays a vital role in fertilization and the block of polyspermy. The glycoprotein ZP3 induces the sperm acrosome reaction, which is necessary for fertilization. Moreover, as described earlier, CG exocytosis releases proteases that modify or “harden” the ZP and prevent sperm entry following fertilization.

Developmental Determinants of Oocyte Quality

Only a high-quality oocyte will have sufficient developmental potential to complete meiosis, undergo fertilization, and initiate the events of early embryo development prior to implantation in the uterus. Oocyte quality is largely determined by the acquisition of both cytoplasmic and meiotic competence during oogenesis, and these two quality determinants are explained further later.

Cytoplasmic Competence

Cytoplasmic competence refers to the accumulation of key maternal factors during oogenesis. This maternal legacy is critical, since developmental events prior to the activation of the zygotic genome (i.e., completion of meiosis, fertilization, egg activation, and preimplantation embryo development) occur largely in the absence of transcription. Moreover, the stored cellular components of the sperm do not contribute significantly to cleavage-stage embryogenesis. To accumulate these maternal products, the oocyte is one of the most transcriptionally and translationally active cells in the human body. Transcription and translation levels, however, decrease significantly when the oocyte is fully grown.

Transcription is the process by which a cell's DNA is read and turned into RNA, and this is a necessary first step in the production of proteins. Transcription occurs in the cell's nucleus (oocyte GV), and the messenger RNAs (mRNAs) that are to be translated into proteins are transported through nuclear pores into the cell's cytoplasm. In the mouse oocyte, RNA content increases by 300% during its active growth phase, and the fully grown oocyte contains ~200 times as much RNA found in a typical somatic cell (~0.6 ng total RNA) (Eichenlaub-Ritter and Peschke, 2002). Some of the mRNAs are recruited and translated into proteins to meet the metabolic demands of the oocyte, but some are selectively degraded or stored for use in the fertilized egg and early embryo. Whether an mRNA is translated or repressed is regulated in large part by the length of its cytoplasmic polyadenylation (polyA) tail within its 3' untranslated region (Eichenlaub-Ritter and Peschke, 2002). In general, translating mRNAs have long polyA tails, whereas ones that are dormant have short ones.

Translation is the process by which mRNA is converted into proteins, and this occurs in the cell cytoplasm mediated by ribosomes. Active ribosome biogenesis and protein synthesis during oocyte growth are key aspects of cytoplasmic competence. To accommodate high levels of protein production, oocytes synthesize and accumulate large amounts of ribosomal RNA (rRNA) that are key components of ribosome biogenesis. rRNA synthesis in the growing oocyte is the highest among all cell types, and rRNA accounts for approximately 60%–70% of the total amount of RNA in oocytes. Mouse oocytes rapidly accumulate ribosomes during the initial growth phase, with 95% of the ribosomal pool established when the oocyte is only two-thirds its terminal size (Eichenlaub-Ritter and Peschke, 2002). Interestingly, several *Drosophila* mutants in ribosomal protein genes have low fertility and reduced fecundity due to defects in oocyte development (Marygold et al., 2007). Thus, ribosome production and protein synthesis are major cellular events during oogenesis that are essential for proper oocyte development.

Meiotic Competence

Meiotic competence refers to the ability of the fully grown oocyte, which is arrested at prophase I, to resume the cell cycle in response to hormonal cues and complete meiosis to ultimately produce a haploid gamete, or a cell that contains half its DNA content. This reduction in DNA content ensures that at fertilization, the unification of a haploid egg with a haploid sperm will produce a diploid zygote with the correct chromosome complement. Central to the oocyte's ability to resume meiosis is global silencing of transcription that is tightly correlated to changes in the oocyte's DNA or chromatin structure. In the prophase-I-arrested oocyte, the configuration of chromatin is classified in one of the three ways: nonsurrounded nucleolus (NSN), intermediate, and surrounded nucleolus (SN) (De La Fuente, 2006). The NSN chromatin configuration is characterized by uncondensed chromatin and is found in smaller, growing oocytes that are actively transcribing their DNA. In contrast, the SN configuration is characterized by condensed chromatin that forms a tight ring around the nucleolus and is associated with fully grown oocytes that are transcriptionally silent. The intermediate configuration is somewhere between the NSN and SN states. In general, oocytes that are in the SN configuration have an increased ability to resume and complete meiosis.

Meiosis resumes in the prophase-I-arrested oocyte at the time of ovulation, which can happen anytime between puberty and menopause. The ovulatory luteinizing hormone (LH) surge from the anterior pituitary triggers the resumption of meiosis. LH binds

to its receptors in the mural granulosa cells of the ovulatory antral follicle and trigger signaling pathways that decrease NPR2 activity and the production of cGMP (Jaffe and Egbert, 2017). As a result, cGMP in the oocyte diffuses down its concentration gradient, which results in a decrease in cGMP levels in the oocyte. This decrease in oocyte cGMP relieves the inhibition of PDE3A and causes a decrease in cAMP levels in the oocyte, triggering cell cycle resumption. Importantly, simply removing the oocyte from the context of the follicle will lead to a drop in cAMP levels, which will result in spontaneous resumption of meiosis.

Once the oocyte resumes meiosis, it will undergo events that are collectively referred to as meiotic maturation. One of the first manifestations of meiotic maturation is the breakdown of the nuclear envelope or GV breakdown (GVBD). During GVBD, the chromosomes will condense completely, and the meiotic spindle will begin to form. The meiotic spindle is the cellular machinery that segregates chromosomes and mediates cell division. At metaphase of meiosis I (MI), the chromosomes will align in the center of the meiotic spindle. Once chromosomes are stably attached to the meiotic spindle, the first meiotic division will occur with the segregation of chromosomes and extrusion of the first polar body. The polar body is the by-product of a meiotic cell division that contains excess DNA. Immediately following MI and without an intervening round of DNA replication, the oocyte will proceed into meiosis II (MII), rapidly reform a spindle, and arrest at metaphase of MII. Once at MII, the cell is termed an “egg” and is capable of fertilization if sperm are present. It is not until fertilization occurs that the second meiotic division will be completed with an additional round of chromosome segregation and extrusion of the second polar body. Both cell divisions at MI and MII are asymmetrical, such that both polar bodies are small to ensure that the bulk cytoplasm remains in the egg cell that will ultimately contribute its contents to the embryo.

Factors That Influence Oocyte Quality

According to dogma, the number of oocytes in the ovary is fixed and nonreplenishable. Thus, the approximate 400 oocytes that are ovulated over a human female’s reproductive life span have existed within the ovary for up to decades. These cells, therefore, are particularly susceptible to accumulated damage due to a variety of factors including aging, obesity, clinical conditions, medical interventions, and environmental exposures, which are discussed further later.

Age

Advanced reproductive age, which typically refers to females > 35 years of age, is associated with a significant decline in oocyte quantity. Females are born with ~1 million oocytes (enclosed in primordial follicles) in the ovary, and this number declines steadily with age, such that the ovary contains ~400,000 oocytes at puberty and only ~1000 at menopause (Broekmans et al., 2009). Paralleling the decline in oocyte quantity is a deterioration in oocyte quality with age (Broekmans et al., 2009). Advanced reproductive age, for example, is unequivocally associated with an increase in oocytes with the incorrect chromosome number—or aneuploidy. Aneuploidy in the female gamete results from errors in meiosis and is a leading cause of infertility, miscarriages, and birth defects. The most common example of age-related aneuploidy is trisomy 21 or Down syndrome. The mechanisms underlying the age-associated increase in aneuploidy are complex and multifactorial, including alterations in chromosome structure, chromosome-associated proteins, cell cycle regulators, and the cell division machinery (Chiang et al., 2012). In addition, oocyte aging is also associated with significant changes in the mitochondria, including decreased function (i.e., energy production) and increased frequency of mitochondrial DNA mutations (May-Panloup et al., 2016). The ovarian microenvironment in which oocytes develops becomes fibrotic and highly inflammatory with age, and this likely indirectly affects oocyte quality (Briley et al., 2016). The overall impact of reproductive aging on fertility is becoming a tangible concern as more women worldwide are delaying childbearing.

Obesity

In addition to aging, obesity impacts oocyte quality. Obesity, defined as having a body mass index of $> 30 \text{ kg/m}^2$, has reached epidemic proportions—affecting > 10% of the world’s adult population. Maternal obesity has been linked to difficulty in conception and adverse fetal health outcomes. Studies in various genetic and diet-induced obesity mouse models have shown that oocytes from obese mice, relative to controls, have reduced size, altered gene expression patterns and epigenetic modifications, defects in meiosis and meiotic spindle formation, aberrant mitochondria, and increased levels of apoptosis (Broughton and Moley, 2017). Interestingly, when examining the effect of obesity on offspring health, pups from obese mothers were initially smaller than those from control mice (Jungheim et al., 2010). However, the pups from the obese mothers ultimately showed signs of metabolic syndrome (glucose intolerance and increased cholesterol and body fat). Maternal programming of metabolic disease can be passed through the female germ line across multiple generations through the transfer of aberrant oocyte mitochondria (Jaeger et al., 2017).

Clinical Conditions and Medical Interventions

There are several clinical conditions or medical interventions that can also impact oocyte quality. For example, maternal diabetes can result in miscarriages and poor pregnancy outcomes due in part to poor oocyte quality (Wang and Moley, 2010). In mouse models of maternal acute and chronic insulin-dependent diabetes, oocytes were smaller and had a decreased ability to progress through meiosis relative to controls. These oocytes were also surrounded by somatic cells with higher levels of apoptosis. Diabetic

mouse ovaries had reduced connexin-43 expression, which may be a potential mechanism underlying the observed defects in oocyte quality. Connexin-43 is a gap junction protein that allows for granulosa cells that surround the oocyte to communicate with each other. Eliminating this essential connexin likely negatively impacts granulosa cell function and alters bidirectional communication with the oocyte, which is required for gamete quality.

Another condition in which oocyte quality is compromised is polycystic ovarian syndrome (PCOS). PCOS is the most common heterogeneous endocrine disorder in reproductive age women, with a prevalence of ~5%–10%. Criteria for diagnosis include elevated androgen levels; ovulation that is infrequent, irregular, or lacking; and the presence of multiple cysts on the ovaries. Women with PCOS suffer from infertility even when using assisted reproductive technologies, and this is in part due to poor oocyte quality. In fact, oocytes from women with PCOS have reduced expression of critical oocyte-specific paracrine factors (i.e., GDF9) and have altered growth dynamics within the follicle (Dumesic and Abbott, 2008). Ovaries from women with PCOS have excess extracellular matrix components, and the ovarian microenvironment in which oocytes develop is more rigid (Wood et al., 2015). Data in the mouse show that follicles grown in rigid biomaterials that mimic the PCOS ovary produce higher levels of androgens relative to estrogen and contain poor-quality oocytes that have compromised developmental competence (Woodruff and Shea, 2011). In addition, there is a higher frequency of insulin resistance and obesity in women with PCOS, and as described earlier, these factors on their own can contribute to reduced oocyte quality and difficulty with conception.

Medical interventions for various clinical conditions can also have the unintended consequence of damaging oocytes. For example, life-preserving cancer treatments—such as chemotherapy and radiation—can trigger DNA damage and cell death pathways in the oocyte. In fact, the oocyte is highly sensitive to such exposures. The dose of radiation sufficient to destroy half the population of human oocytes is <2 Gy (Wallace et al., 2003). Because the number of oocytes in the ovary is nonreplenishable, oocyte loss due to chemotherapy- or radiation-induced damage can accelerate reproductive aging and lead to early onset menopause. The effect of cancer therapies on reproduction is significant because a greater number of women, men, and children are surviving their cancer diagnoses, and long-term quality-of-life factors such as fertility and normal reproductive function post cancer are of paramount importance. This need has resulted in the generation of a new field of oncofertility that bridges oncology and reproduction to explore and expand the fertility preservation options and the reproductive potential of those with cancer (Woodruff, 2015).

Environmental Exposures

Exposures to several chemicals in the environment are also harmful to oocytes. One primary example is bisphenol A (BPA), a compound that is widely used in the production of plastics, resins, and epoxies (Sartain and Hunt, 2016). The chemical structure of BPA is similar to estrogen and is weakly estrogenic. Thus, it acts as an endocrine disruptor. After prolonged exposure, BPA may be found in many biological fluids, including blood, urine, amniotic fluid, cord blood, breast milk, and follicular fluid. In the mouse model, BPA exposure significantly disrupted various aspects of meiosis in oocytes and resulted in spindle abnormalities and increased aneuploidy. A similar phenotype has also been observed in human oocytes. Chronic low exposure to BPA during oocyte growth can also disrupt the epigenome of the oocyte by altering methylation of imprinted genes. The exact molecular mechanisms by which BPA leads to these outcomes are an active area of investigation. Importantly, transgenerational effects have been observed in the offspring of BPA-exposed rodents, so perturbations that occur in the oocyte may have impacts not only on fertility but also on the health of future generations.

Outlook

The oocyte has the great potential of transforming into another living organism. Understanding the biological mechanisms regulating how this cell develops and what factors impacts its quality has significant impact for the health and well-being of subsequent generations. In addition, recent scientific and technological advances are changing the way we think about reproduction. In the not-so-distant future, oocytes not only will develop within ovaries but also will be derived from induced pluripotent stem cells and gonadal bioprotheses. For these ex vivo approaches to be successful, we must recapitulate key aspects of in vivo development and understand how these in vitro manipulations affect the resulting oocyte.

Acknowledgments

The authors thank Dr. Karen Schindler and Dr. Teresa Woodruff for the critical review of the manuscript and Dr. Atsuko Kato and Shawn Briley for providing images. This work was supported by the Master of Science in Reproductive Science and Medicine Program and the Center for Reproductive Health After Disease (P50 HD076188) from the National Centers for Translational Research in Reproduction and Infertility (NCTRI).

Glossary

Ovarian stroma Soft tissue of the ovary that contains an abundant supply of blood vessels and surrounds the functional units, follicles and corpora lutea.

Atresia Designation for programmed cell death of ovarian follicles by apoptosis.

CYP Cytochrome P450 family of enzymes that actively participate in phase 1 metabolism of many small chemicals. Enzyme activity can include bioactivation or detoxification of a chemical as well as steroidogenesis.

Sex cord stromal tumors Malignancies arising in the ovarian stroma.

PCOS Polycystic ovarian syndrome, associated with menstrual disorders.

Introduction

The stroma of the ovary is a vascularized soft tissue that consists of interstitial cells (Wikipedia). This comprises the compartment that forms the body of the ovary. Interstitial cells pack the areas between the functional units within the ovary, oocyte-containing follicles, and corpora lutea (Fig. 1). Interstitial cells are designated as primary or secondary. Primary interstitial cells originate from fibroblastlike stromal cells. Generally, in species with long gestational periods, they differentiate during fetal development. This is the case in human ovaries where their development is maximal at 18 weeks of gestation (Konishi et al., 1986). Whereas, in species with short gestational periods, they differentiate during the postnatal period. They were even found to develop on different

Fig. 1 The reproductively active mammalian ovary. The major functional unit within the cycling ovary consists of the oocyte-containing follicle. The primordial follicle is formed during fetal development and contains an oocyte arrested in prophase of the first meiotic division. Therefore, after birth, the ovary contains a set number of follicles that must serve the female throughout her lifespan. The oocyte is surrounded by a single layer of squamous granulosa like cells. Primordial follicles may remain dormant for up to a number of years in women, or may become activated toward development to ovulation at any time after birth. Following activation of a primordial follicle, it goes through a number of maturation stages. The first stage is primary in which the surrounding granulosa cells become cuboidal, a sign they are activated and are beginning to function. In the secondary stage, granulosa cells have begun to proliferate and form a multi-layer around the oocyte. At this stage, theca interna cells form an outer layer around the proliferating granulosa cells. As the follicle keeps growing, a fluid filled space within the granulosa-oocyte space called an antrum begins to form. The antrum enlarges and the follicle grows to the pre-ovulatory stage. Following ovulation, the oocyte enters the oviduct for potential ovulation, whereas, residual granulosa and theca cells infiltrate to form a solid gland and differentiate by luteinization to become the corpus luteum (CL). If fertilization of the oocyte has not occurred, the CL undergoes regression and disappears. The vast majority of primordial follicles in the ovaries at birth do not become ovulated, but undergo a form of cell death by apoptosis called atresia. The remainder of the ovary constitutes the stromal compartment comprised of blood vessels and interstitial cells. Reproduced from Hoyer, P. B., Devine, P. J. (2001). postnatal days (pnd) between different strains of rats and mice (Guraya, 1991). Postnatal day 12 was the time of their appearance in C57Bl/6J mice, whereas it was pnd 10 in C57Bl/6Pa mice. They were first observed on pnd 7 in Swiss albino mice. Primary interstitial cells that have developed in the fetal guinea pig ovary, begin to regress during postnatal life (Guraya, 1977). However, factors that regulate this regression are not known. Primary interstitial cells in a number of species possess cytological and ultrastructural characteristics of steroidogenic cells. These characteristics include sudanophilic lipid droplets (staining positive with Sudan black) and orangeles related to steroidogenesis.

Secondary interstitial cells form from residual theca interna cells in atretic follicles (Guraya, 1991). Thus, whereas, primary interstitial cells form the ovarian stroma as the ovary undergoes fetal development, secondary are derived from theca interna remaining after follicular atresia. Theca cells are acquired at the secondary stage during development of a follicle as it is recruited for development toward possible ovulation. However, the vast majority of developing follicles do not ovulate, but undergo cell death by apoptosis (atresia). In the ovary the oocyte is enclosed in a spherical-shaped follicle along with granulosa cells. Theca interna cells surround the membrane a propria that forms the follicle. During follicular development theca interna cells undergo steroidogenesis to produce androgens (androstenedione and testosterone). The androgens passively diffuse across the membrane a propria and are converted to 17 β -estradiol in the granulosa cells. During atresia, the oocyte and its surrounding granulosa cells degenerate, yet, the layer of theca interna cells that surround the follicle remain. These cells form the secondary interstitial compartment. A major function of the theca interna cells is to undergo steroidogenesis, providing substrate for follicular steroid production. As a result, as with primary, secondary interstitial cells display an ultrastructure typical of steroid-producing cells (Konishi et al., 1986).

Genes Expressed

As suggested by morphological evidence, the interstitial compartment appears to be steroidogenic. Investigation of gene expression in the stromal compartment can provide evidence to support that theory. Histochemical analysis of pnd 3 mouse ovaries demonstrated staining for the steroidogenic enzyme 3- β hydroxysteroid dehydrogenase (3 β HSD, Hoyer and Byskov, 1981). Expression of the cytochrome P450 enzyme CYP2B which is involved in phase 1 metabolism of xenobiotics was also demonstrated in interstitial cells in mouse ovaries (Fig. 2). Other studies have also provided evidence of 3 β HSD activity in rat ovaries (Presl et al., 1964; Schlegel et al., 1967). Tsai-Morris and Johnson (1982) demonstrated 17 α -hydroxylase activity by conversion of 17 α [³H]-pregnenolone to 17 α [³H] progesterone in primary interstitial membranes of immature ovaries.

According to reported high throughput analysis of human ovarian stromal cells, 879 proteins were determined to be expressed (LifeMap). Expression of these gene products is also supported by morphological observations of rough endoplasmic reticulum and ribosomes in intermediate stages of primary interstitial cell differentiation (Guraya, 1991).

Rat mature interstitial cells have also been shown to express receptors for androgen (AR), estrogen (ER), and luteinizing hormone (LHR). It was reported that injection of adult female rats with testosterone propionate induced the appearance of aged interstitial cells with enhanced expression of AR, but reduced ER and LHR expression, compared with normal mature interstitium (Bukovsky et al., 2002). This resulted in premature aging of adult rat ovaries.

Functional Significance

The functional significance of ovarian stroma is not completely understood. Much morphological information has been described, and a large number of genes have been demonstrated to be expressed in interstitial cells. However, what functional capacity these genes have has been hard to determine. This is partly due to the difficulty of separating interstitial cells from the dynamic compartments within the ovary, follicles and corpora lutea. There is ample evidence that the tissue is steroidogenic as has been discussed above, but whether steroid produced in those cells supplements that produced in follicles (androgens and 17 β -estradiol) and corpora lutea (progesterone) is not clear. A recent immunohistochemical study of stromal cells adjacent to epithelial ovarian tumors in women found that the stroma in those ovaries express markers of sex-steroid differentiation and steroidogenic enzymes (calretinin, inhibin, steroidogenic factor 1; Blanco et al., 2017). Further, this tissue expressed genes involved in steroid hormone biosynthesis (CYP17, CYP 19, HSD17B1, AKR, C3). The growth of ovarian neoplasms is known to be stimulated by steroid hormones. This led the authors to propose that the stroma surrounding ovarian epithelial tumors elaborates steroid hormones to further stimulate neoplastic growth.

Isolation of Interstitial Cells

Many studies of the stromal compartment have focused on cytological and ultrastructural imaging of ovarian sections. However, in vitro incubation of neonatal whole ovaries from laboratory animals cannot distinguish steroid production from follicular versus interstitial cells. Thus, performing in vitro biochemical or molecular studies of interstitial cells might involve separating them from within the ovary. This could be done on isolated ovaries that were gently dissociated with collagenase (Flaws et al., 1994). By this method, follicles remain intact and the dissociate can be filtered through a 250 μ pore membrane which will retain the intact

Fig. 2 Ovarian distribution of CYP2B protein in ovarian follicles and interstitial tissue. B6C3F1 mice (day 28) were given a daily injection (15d, i.p.) of sesame oil (vehicle control) or 4-vinylcyclohexene (VCH; 7.4 mmol/kg/d). Ovaries were removed 4 h. after the final injection and processed for immunostaining by confocal microscopy. CYP2B protein was visualized in small preantral (F1), early antral (F2), and antral (F3) follicles with high intensity staining in the interstitial compartment (Int). Ovaries were from vehicle-treated (A), or VCH-treated (B, C) mice. Ovarian section stained with YOYO-1 and CY5, with no primary antibody added (D). Green stain = YOYO (DNA stain). Red stain = CY-5 labeled antibody for CYP2B. Modified from Cannady, E. A., Dyer, C. A., Christian, P. J., Sipes, I. G., Hoyer, P. B. (2003). Expression and activity of cytochromes P450 2E1, 2A, and 2B in the mouse ovary: The effect of 4-vinylcyclohexene and its diepoxide metabolite. *Toxicological Sciences* **73**, 423–430, with permission from Toxicological Sciences.

follicles and the filtrate will be highly enriched in interstitial cells. NOTE: It is important to use ovaries collected during the follicular development stage to avoid collecting luteal cells, which would also be dissociated by collagenase, and thereby contaminate the interstitial fraction.

Pathological Involvement

Ovarian stromal tissue can develop into malignancies. This is often termed sex cord-stromal tumor. This classification of ovarian tumor, however, is rare comprising about 7%, when compared with other categories of malignant ovarian neoplasms (Colombo et al., 2007). Sex cord stromal tumor is usually composed of various combinations of granulosa, theca and luteal cells. These can be classified as granulosa cell tumors or thecomas. The ultimate classification of these tumors as sex cord-stromal can only be confirmed by histological evaluation which reveals predominately solid cellular tumor with components of variable mixtures of granulosa, theca and fibroblast cells. Immunohistochemical analysis of stromal cell ovarian tumors observed expression of the steroidogenic enzymes 17 α hydroxylase and 3 β HSD (Ishikura and Sasano, 1998).

CYP450 aromatase is usually expressed in follicular granulosa cells, where high levels of estrogen are produced by large antral pre-ovulatory follicles. Aromatase expression in granulosa cells is regulated by follicle stimulating hormone (FSH) produced in the anterior pituitary. Under normal conditions, pituitary hormone secretion is kept relatively low due to negative feedback from ovarian hormones. However, CYP450 aromatase, was exclusively expressed in stromal cells of ovarian tumors (Kato et al., 2013).

Sex cord-stromal tumors are most prevalent in post-menopausal women. One hypothesis to explain this age group distribution of the disease is that, after oocyte depletion (menopause) negative feedback from the ovary is lost, resulting in increases in the pituitary hormones FSH and luteinizing hormone (LH) which in turn stimulate tumor growth (Colombo et al., 2007).

Another disorder that involves ovarian stroma is polycystic ovarian syndrome (PCOS). PCOS is an ovarian syndrome that affects 5%–10% of reproductive age women worldwide (Chun, 2014). Two of three criteria must be met to support a diagnosis of PCOS (Guraya, 2013). The three criteria are oligo or anovulation (dysmenorrhea), hyperandrogenism, and ultrasonographic evidence of the presence of > 12 follicles in either ovary measuring 2–9 mm in diameter. The presence of multiple large follicles can contribute to increased ovarian volume. One cardinal feature of PCOS as visualized by ultrasonography has been the presence of a bright, highly echogenic stroma (Buckett et al., 1999). In this study, a stromal index was calculated (ratio of mean stromal echogenicity to mean echogenicity of the entire ovary). Total stromal echogenicity was also calculated. Ovarian volume, stromal volume and stromal peak blood flow velocity were significantly higher in ovaries from women with PCOS compared with those from normal women. The stromal index was increased in PCOS ovaries likely due to increased volume of the ovarian stroma. However, the mean stroma echogenicity was not different between PCOS and normal patients, likely due to overall lower mean echogenicity of the entire ovary in PCOS women.

In summary, the stroma of the ovary has not been as widely studied as its functional units, follicles and corpora lutea, however, it serves an important role in providing the architecture to support follicular development, ovulation and luteinization. Additionally, steroid production by interstitial cells is likely to contribute to the regulation of ovarian function under normal and pathological conditions.

Cell-to-Cell Communication in the Ovarian Follicle

Establishment of the Ovarian Reserves

In order to grasp the significance of the main signaling pathways occurring within the ovary, it is helpful to understand how the ovarian reserves are established. During fetal development, primordial germ cells migrate to the gonadal ridge, which will form the gonads (Wear et al., 2016). In females, these cells proliferate and interconnect with surrounding somatic cells to form cysts (Greenbaum et al., 2011). The ovarian reserves are established through a selection process in which apoptosis eliminates most of these cysts. Those that are selected will become primordial follicles (Wear et al., 2016). In cattle and humans, the number of oocytes apparently peaks at about 5 million in the developing fetus and then plummets to an average of about 300,000 per ovary at birth, with a range of 35,000–2.5 million (Erickson, 1966; Wallace and Kelsey, 2010). In most species, primordial follicles are composed of a single oocyte surrounded by a few flattened somatic cells. Canine follicles have been reported to harbor more than one oocyte (Payan-Carreira and Pires, 2008).

These systemic signaling pathways are active to various degrees throughout the lifetime of the animal. Non-ovulatory waves of follicular cell proliferation occur already during fetal growth and then become dormant around the time of birth. Ovulatory follicular waves begin at puberty and then occur more or less regularly, peaking in reproductive potency and then declining until the end of reproductive life, at which point the ovarian reserves are depleted. The gradual faltering of signaling that occurs as menopause is reached is well documented (Prior and Hitchcock, 2011). In contrast, little is known about what switches the signaling on at puberty to initiate reproductive life. Discovered in 1997, neuropeptides known as kisspeptins appear to initiate GnRH secretion by the hypothalamus (Messenger et al., 2005).

The growth and differentiation of the cells surrounding the oocyte in the sexually mature animal is called folliculogenesis, whereas the growth and differentiation of the cell destined to yield an ovule is called oogenesis. Throughout folliculogenesis, the somatic cells forming the follicles proliferate and differentiate to become a highly structured unit (Fig. 1). Once recruited

Fig. 2 Chronology of folliculogenesis in the human ovary. gc, granulosa cell. From Gougeon, A. (1986). Dynamics of follicular growth in the human: A model from preliminary results. *Human Reproduction* 1, 81–87.

from the stored pools, primordial follicles will develop into primary follicles, which are characterized by the presence of cuboid cells surrounding the oocyte. As somatic cell proliferation progresses, the oocyte grows in volume. The secondary follicle stage is reached when the oocyte is enclosed in a few layers of somatic cells called granulosa cells, which are further enclosed within an extracellular collagen matrix called the basal lamina. Somatic cells attached to the outside surface of the basal lamina are called theca cells. As the follicle develops, an antrum is formed among the granulosa cells and becomes filled with follicular fluid. The presence of this fluid-filled cavity marks the tertiary follicle stage. Although our general model of endocrine signaling implies a menstrual/estrus cycle lasting 23–35 days in humans (Munster et al., 1992), 18–24 days in cattle (Adams et al., 2008) and only 4 or 5 days in mice and rats (Felicio et al., 1986), the entire process of primordial follicle recruitment up to ovulation spans a much longer period of time. Bringing a human primordial follicle to the early tertiary follicle stage may take up to 300 days, followed by another 50 days to bring a follicle with a small antrum to the pre-ovulatory stage (Gougeon, 1986). It takes about a year (or 13 menstrual cycles) for a primordial follicle to reach ovulation size. In pre-pubertal gilts (the porcine equivalent of a heifer), the time from follicular activation to ovulation has been estimated at 100 days (Morbeck et al., 1992). In cattle, antral growth alone takes 40 days to complete (Lussier et al., 1987) whereas in mice, folliculogenesis overall appears to require only 17–19 days (Pedersen, 1970). In order for each menstrual/estrus cycle to result in ovulation, follicles are recruited in waves. When a wave of antral follicles is being monitored, subsequent waves are already in preparation. Most of our understanding of endocrine control of folliculogenesis is based on monitoring the final interval of gonadotropin-responsive antral growth leading to ovulation (the last 20 days in Fig. 2). It is known that in cattle at least, this interval does not correspond to the entire estrus cycle (18–24 days) and that two or three cohorts of follicles may grow and die during this period (Evans, 2003). The human menstrual cycle might also coincide with two or three follicular waves (Baerwald et al., 2012). When considering endocrine support for ovulatory waves in cattle, and possibly in humans, the monitoring period should therefore span 8–10 days. Our understanding of the intra-follicular communications occurring during this final phase (i.e., antral growth) is much more detailed than our understanding of the signaling occurring during the follicular recruitment and basal growth phases or throughout folliculogenesis overall.

Intra-Follicular Signaling

Signaling inside the follicle is complicated. It must first ensure a proper response of follicular cells to the systemic support provided by the HPX axis gonadotropins. This occurs mainly through transduction of external signals to intercellular communications. Since

the follicle and the gamete behave like a syncytium of inter-dependent cells, signals from the follicle center (i.e., the oocyte) reach peripheral follicular cells and vice versa. This bi-directional communication allows maintenance of synchrony between follicular development and oogenesis. Asynchrony between the follicular compartment and the gamete will lead to the demise of the follicle and hence to reduced fertility or even infertility.

Recruitment

Intercellular communications during the recruitment phase of folliculogenesis is only partially understood. Gene inactivation studies of reproductive phenotypes characterized by high turnover of primordial follicles have allowed identification of the currently known regulators of recruitment. Some genes appear to enhance recruitment rate, thus leading to faster depletion of the ovarian reserves, while others lead to infertility due to inability of the activated primordial follicles to progress through folliculogenesis, caused by blockage of proliferation and differentiation of the somatic cells surrounding the oocyte.

Follicle recruitment is gonadotropin-independent (Glasier et al., 1989), and current understanding based on gene expression studies suggest that inhibitory signals play a major role by keeping primordial follicles in latency. Among the suppressors of recruitment is the anti-Müllerian hormone (AMH), of which the inactivation (by suppressing gene expression) appears to stimulate recruitment, whereas supplementing in vitro cultures of ovarian cortex with AMH suppresses follicular recruitment and growth (Durlinger et al., 1999). AMH is expressed in the somatic cells surrounding the oocyte (Visser et al., 2006). Other suppressors originating from the oocyte itself have appeared to be part of the PTEN–PI3K–AKT–mTOR canonical pathway (Kim, 2012). Inactivating genes such as *phosphatase and tensin homolog (PTEN)* or *mechanistic target of rapamycin (mTOR)* and the corresponding driver molecules tuberous sclerosis 1 and 2 (Tsc1 and Tsc2) lead to over-active recruitment of primordial follicles and subsequently to rapid depletion of reserves (Reddy et al., 2008; Adhikari et al., 2009). A similar phenotype has been obtained by depleting downstream effector molecules such as forkhead box O3 (Castrillon et al., 2003). In many cell types, growth-factor-mediated stimulation of the PTEN–PI3K–AKT–mTOR pathway leads to increased gene translation as result of phosphorylation of ribosomal proteins (Kim, 2012). Although depletion of these growth factors is associated with follicle recruitment, it is still unclear what triggers the shift from the inhibited state. Nerve growth factor and brain-derived neurotrophic factor might be involved (Spears et al., 2003), as might positioning of the primordial follicle within the ovarian cortex, which could act through physical pressure, since infertile patients with normal ovarian reserves but very low antral follicle counts have responded well to incisions made on the ovary surface to the release intra-ovarian pressure (Eftekhari et al., 2016). Since the Hippo pathway is involved in limiting organ size, and in the case of ovaries its activity would result in pressure on resting follicles, it has been proposed as a long-term negative regulator of follicle recruitment (Kawamura et al., 2013).

Basal Growth

A variety of other factors could also impede the lengthy process by which primordial follicles progress towards ovulation. Bidirectional communication between the somatic cells and the gamete is important even at the earliest stage of folliculogenesis. Since the immature oocyte inside a primordial follicle is embedded amidst flattened somatic cells in direct contact with each other (Fig. 1), inter-cellular signaling likely occurs through autocrine and paracrine mechanisms with passage of molecules through gap junctions between plasma membranes (Gittens et al., 2005; Luciano et al., 2011).

One of the first communication routes found to function throughout folliculogenesis is the tandem composed of the tyrosine protein kinase receptor (expressed in the oocyte) and its ligand, secreted by the somatic cells (Driancourt et al., 2000). This receptor–ligand interaction is important for antrum formation and oocyte survival.

Many members of the transforming growth factor beta (TGFB) superfamily also appear to mediate communication between the gamete and the somatic cells. One of the key members is growth differentiation factor 9, which is produced by the oocyte and promotes expression of the tyrosine protein kinase ligand and the LH receptor and stimulates the somatic cells to proliferate and differentiate, showing the central role of the gamete in follicle development (Su et al., 2004). In the absence of GDF9, the primordial follicle fails to complete the transition to the primary follicle stage. Other members of the TGFB superfamily shown to play a functional role early in folliculogenesis are bone-morphogenic proteins (BMP) 2, 4, 6, 7 and 15, as illustrated in Figs. 3 and 4 (Chang et al., 2016).

Several additional members of the TGFB superfamily appear to be involved in folliculogenesis during the long basal growth period. These include fibroblast growth factor 2, platelet-derived growth factor, leukemia inhibitory factor and other neurotrophins, in particular NGF and BDNF (Pangas and Matzuk, 2004). It is still unclear how these factors are regulated and how essential they are, since in vitro culture of ovarian cortex leading to follicular development has been achieved successfully in serum-free media, thus in the absence of a complex mixture of growth factors (Eppig and O'Brien, 1996; Xiao et al., 2015).

Although the complexities of the interplay between these molecules are not yet understood, it is known that the transduction of their signals is mediated in large part by the SMAD pathway (Pangas, 2012). SMAD factors can translocate to the nucleus to act within transcriptional complexes and target transcription factors such as forkhead box L2, spermatogenesis and oogenesis-specific basic helix-loop-helix 1 and 2 (SOHLH1, SOHLH2), LIM homeobox 8 (LHX8), newborn ovary homeobox (NOBOX) and folliculogenesis-specific basic helix-loop-helix (FIGLA), as illustrated in Fig. 5 (Lim and Choi, 2012). Inhibition of SMAD

Fig. 3 Various factors, such as TGFB superfamily, are implicated in the bidirectional communication between the gamete and the somatic cells. From Young, J. M. And Mcneilly, A. S. (2010). Theca: The forgotten cell of the ovarian follicle. *Reproduction* **140**, 489–504.

signaling also inhibits folliculogenesis very early on (Kaivo-Oja et al., 2006). The role of these factors appears to be to activate genes involved in the growth and morphogenesis of both the somatic cells and the oocyte (Pangas and Matzuk, 2004).

In mice, zona pellucida glycoproteins are secreted solely by the oocyte, whereas in pigs and horses, the somatic cells also participate in this secretion (Flechon et al., 2003; Kolle et al., 2007). Connectivity through the physical boundary formed by the zona pellucida between the oocyte and the somatic cells is maintained through the formation of filipodia-like cellular projections by the somatic cells, as illustrated in Fig. 6 (Allworth and Albertini, 1993; Macaulay et al., 2014). These span the zona pellucida and attach to the oocyte plasma membrane. Such transzonal projections are conserved across species, since they play a major role in nourishing the developing oocyte (Allworth and Albertini, 1993; Macaulay et al., 2016). Various types of physical bridges between somatic cells have been described, such as tunneling nanotubes and epithelial bridges, which have been shown to allow exchanges of material and even mitochondria between cells (Zani and Edelman,

Fig. 6 Transzonal projection structure. (A) Scanning electron micrograph of a cumulus cell (CC) and its TZP interaction with the zona pellucida (ZP). (B) A TZP that penetrates the ZP and interacts with the microvilli (Mv) extensions of the oocyte's (Oo) oolemma. (C) and (D) Numerous actin microfilaments in projections interact with the oocyte membrane. From (Macaulay, A. D., Gilbert, I., Caballero, J., Barreto, R., Fournier, E., Tossou, P., Sirard, M. A., Clarke, H. J., Khandjian, E. W., Richard, F. J., Hyttel, P. and Robert, C. (2014). The gametic synapse: RNA transfer to the bovine oocyte. *Biology of Reproduction* **91**, 90.

2010; Torralba et al., 2016). It has been shown that in transzonal projections, the plasma membranes of the different cells do not fuse (Macaulay et al., 2014). The points of contact are thus gap junctions (Luciano et al., 2011). These channels allow the passage of small molecules (<1 kDa) including cyclic nucleotides (cAMP and cGMP) from the somatic cells in order to maintain the oocyte in meiotic arrest (Gilchrist et al., 2016). Little is known about the nature and the extent of transfers mediated via transzonal junctions from the basal growth phase up to the secondary follicle phase, at which point several layers of granulosa cells and presumptive theca cells are differentiating into a fully formed antral follicle.

Antral Development

The redistribution of granulosa cells to form an antrum marks the passage of the follicle to the tertiary phase. Such a follicle is composed of various cell types, the outermost being more or less flattened cells making up the theca *externa*, in contact with rounder cells making up the theca *interna*, both separated from the granulosa cells by the basal membrane, and finally the innermost and largest cell, namely the oocyte (Fig. 1). Granulosa cells are further delineated according to their position relative to the oocyte. Mural granulosa cells line the entire inner surface of the follicle, while cumulus cells lie closer to the gamete. Cells in direct contact with the oocyte through transzonal projections (via the zona pellucida) make up what is called the *corona radiata*. From primordial follicle activation through basal growth up to the development of the antrum, folliculogenesis seems to depend mostly on local signaling supported by endocrine stimulation. In antral follicles, an important change occurs, making them responsive to gonadotropins (Hillier, 2001) and activating a new set of intra-follicular communications. The two-cell, two-gonadotropin model proposes that pulses of LH stimulate receptors on the surface of theca cells, inducing cholesterol uptake and production of androstenedione by CYP17 activity (Hillier, 2001; Hillier et al., 1994). The neighboring granulosa cells take up the androgen, while stimulation of their FSH receptors activates CYP19 to convert the steroid to estradiol (Fig. 7). In some species, receptor expression is not restricted to one follicular compartment (Peng et al., 1991; Yung et al., 2014) and both receptors are coupled to intracellular signaling mediated by the cAMP-protein kinase A pathway (Gloaguen et al., 2011). In mono-ovulating species, follicles are selected, and this is believed to occur when granulosa cells differentiate to acquire LH receptors, thereby becoming responsive to the basal LH pulses and the pre-ovulatory LH surge and therefore insensitive to the negative feedback of estradiol on FSH secretion (Fortune et al., 2001). FSH stimulation activates epidermal growth factor signaling inside the follicle (El-Hayek et al., 2014).

Most models incorporate the notion of highly compartmentalized follicles in which the different types of granulosa cells (i.e., mural, cumulus and the *corona radiata*) have different functions, as exemplified by differences in the sets of expressed genes. In the late stages of folliculogenesis, the follicular cells and the gamete are still in bilateral communication. Oocyte-secreted factors (e.g., growth differentiation factor 9 and bone-morphogenic protein 15) promote granulosa cell proliferation, and it is believed that gonadotropin signaling is amplified, since it is transmitted over a decreasing LH receptor expression gradient from the outside of the follicle towards the gamete (Gilchrist et al., 2004). This may be important given that once the oocyte reaches its full size, its chromatin becomes compacted and transcription ceases (Lodde et al., 2008; Tan et al., 2009). Although this compaction is species-specific, transcriptional silence means in any case that the oocyte is less capable of responding to environmental cues and must rely on its stored reserve of transcripts to produce its proteins (De La Fuente and Eppig, 2001).

Fig. 7 Illustration of the two-cell, two-gonadotropin model. From Stocco, C. (2008). Aromatase expression in the ovary: Hormonal and molecular regulation. *Steroids* 73, 473–487.

Corona radiata cells bearing transzonal projections have a nourishing role that includes continued delivery of cyclic nucleotides to the gamete to maintain meiotic arrest as well as providing energy substrates such as pyruvate and lactate (Scantland et al., 2014). In many species, the oocyte contains immature mitochondria and an inactive glycolytic apparatus and needs a supply of 3' carbon substrates in order to maintain at least some energy production by oxidative phosphorylation (Rieger and Loskutoff, 1994; Trimarchi et al., 2000).

In addition to proximal cell-to-cell communications, paracrine signaling through the follicular fluid occurs. The composition of antral fluid is quite similar to that of serum and fluctuates during the menstrual or estrous cycle. It contains ions, proteins, hormones, lipids and energy substrates and even accumulates toxins such as organochlorines (Leroy et al., 2004; Meeker et al., 2009). The differences in composition between antral fluid and serum suggest selective transport from one to the other as well as accumulation of substances secreted by follicular cells. Among these, certain proteins are believed to sequester insulin-like growth factors, thereby controlling ovarian stimulation (Amato et al., 1999). In follicles at the early antral stage, this sequestering lasts until pregnancy-associated plasma protein A intervenes to potentiate a pre-ovulatory surge of stimulation (Nyegaard et al., 2010). Communication in pre-ovulatory follicles also involves paracrine signaling among the different types of granulosa cells. Following stimulation by LH, epidermal-growth-factor-like substances (epiregulin, amphiregulin, and betacellulin) are expressed as precursor hormones at the surface of mural granulosa cells. Matrix metalloproteinases cleave the precursor protein to release the hormone subunit into the follicular fluid, which binds to its target receptors on cumulus cells, as illustrated in Fig. 8 (Conti et al., 2006; Hsieh et al., 2009; Light and Hammes, 2015). Signal transduction occurs through the MAPK/ERK pathway to stimulate cumulus cells in preparation for ovulation (Fan et al., 2009). Another signaling molecule requiring proteolysis is the C-type natriuretic peptide (NPPC). The precursor protein and its receptor are expressed in granulosa and cumulus cells (Zhang et al., 2010; Franciosi et al., 2014). Cleavage of the precursor releases a peptide 22 amino acid residues in length, which signals the follicle to grow and maintain the oocyte in meiotic arrest (Franciosi et al., 2014; Zhang et al., 2010).

More recently, follicular cells have been shown to secrete extracellular vesicles into the antral fluid for absorption by cumulus cells (da Silveira et al., 2012; Di Pietro, 2016). The protein and RNA contents of these microvesicles and exosomes could fluctuate during the menstrual (or estrous) cycle and reflect the metabolic status of the mother. These vesicles might constitute another signaling route, and their composition could indicate both follicle viability and oocyte quality. Although the gamete itself appears to have a very limited capacity for exosome uptake, the surrounding cumulus cells could provide an entry point and deliver the contents to the oocyte. Although it was believed that transzonal projections are closed-ended and that only small molecules (<1 kDa) such as cAMP, cGMP, energy substrates and miRNAs are transferred through gap junctions, the presence of microvesicles at junctions and transfer of mRNA and lipids from cumulus cells to the oocyte through transzonal projections have been demonstrated recently (Macauley et al., 2014, 2016; Del Collado et al., 2017). The transfer of large cargo to the oocyte is well described in invertebrates such as *Drosophila* and hydra, where nurse cells “dump” nearly all their contents (including organelles other than the nucleus) into the oocyte. In *Xenopus*, nurse cells transfer germ-cell granules containing mRNA and ribosomes to the oocyte (Guild et al., 1997; Alexandrova et al., 2005).

Folliculogenesis and Developmental Competence of the Oocyte

Folliculogenesis and oogenesis progresses concomitantly until the oocyte reaches its full size. In mice, fully grown oocytes are found in antral follicles up to 2 mm in diameter and ovulatory follicles can reach 4 mm (Griffin et al., 2006). In humans, full-sized oocytes are found in antral follicles 5–7 mm in diameter, and the diameter of a follicle at ovulation is about 20 mm (Gougeon, 1986). In cattle, full-sized oocytes are found in 3 mm follicles and ovulation occurs 7–8 days later in a follicle 20–25 mm in diameter (Fair et al., 1995). Folliculogenesis therefore continues sometimes for several days after the oocyte has reached its full size and passed the chromatin compaction stage (Lodde et al., 2008; Tan et al., 2009). At this point, corona radiata cells could act as surrogate nuclei, much like nurse cells do, and support the transcriptional needs of the gamete during the final stage of folliculogenesis.

Regarding the capacity of the oocyte to undertake the post LH surge steps, it should be considered that full-sized oocytes collected from follicles that have not reached ovulation size are sometimes already developmentally competent, in terms of zygote formation and subsequent embryogenesis at least up to the blastocyst stage. In cattle for example, oocytes from follicles smaller than 2 mm are undersized and incapable of resuming meiosis, whereas a large proportion of oocytes from follicles from 3 to 6 mm are able to reach metaphase II in vitro (Fair et al., 1995). About 30%–40% of these are able to form a zygote and develop into a blastocyst in vitro, compared to about 60% of oocytes collected from healthy follicles larger than 8 mm (Rizos et al., 2002). The developmental competence of immature oocytes is highly sensitive to manipulation of the hormonal regimen (Blondin et al., 2002; Nivet et al., 2012). These observations suggest strongly that a considerable proportion of oocytes have already acquired the capability of resuming meiosis, forming a zygote and sustaining early development but that this proportion increases significantly when the oocyte is kept inside the follicle, even if it is full-sized and transcriptionally inactive. The nature of the essential events that occur during the final step of folliculogenesis to ensure the acquisition of developmental competence is still largely unknown, as are the characteristics that define oocyte quality.

It has been observed recently in cattle that the RNA contents of transzonal projections of cumulus oocyte complexes in antral follicles 3–6 mm in diameter increase significantly during the first 4 h following removal of the ovaries from the animal (Macauley et al., 2016). At this point, the oocyte is still in meiotic arrest and resumes meiosis spontaneously once the cumulus oocyte complex is extracted from the follicle (Tsafiri and Pomerantz, 1986). The ability of cumulus cells to react to some unknown cue following removal of the ovary and to keep the oocyte in meiotic arrest (which requires the transfer of cAMP) suggests a parallel signaling within the compartments of a follicle. Furthermore, the timing of post-mortem RNA accumulation matches post-mortem acquisition of developmental competence observed in cattle (Blondin et al., 1997). It is unclear what this means in terms of the natural post-LH surge events that lead to a complete change in communications and transformation of theca and mural granulosa cells into the corpus luteum while cumulus cells begin to express a new set of genes for cloud expansion and disconnection from the oocyte as it resumes meiosis.

Various interesting observations have clarified the role of somatic cells and endocrine signaling in producing developmentally competent oocytes. First it was shown that in vitro culture of mouse follicles can provide oocytes that occasionally yield live offspring (Eppig and O'Brien, 1996) and that culture conditions can be improved in order to increase the percentage of oocytes that do so (Morohaku et al., 2016). It was noted also that stripped oocytes are not competent, but their developmental capacity improves when they are co-cultured with cumulus cells and even more when they are in physical contact with them (Luciano et al., 2005). Meanwhile, as scientists pondered the complex interplay of signaling pathways and systemic as well as local feedback loops, their assumption that these are essential was challenged when mouse oocytes were obtained in vitro from undifferentiated cells originating outside the follicular environment. This was achieved first using primordial germ-cell-like cells (Hayashi et al., 2012) and later repeated using embryonic stem cells and pluripotent cells (Hayashi and Saitou, 2013; Hikabe et al., 2016). Some of these oocytes were competent for fertilization and even underwent embryonic development to produce live offspring (Hikabe et al., 2016). However, the vast majority of them were incompetent, and this was attributed to inadequate endocrine support and physical interaction between somatic cells and the oocyte (Morohaku et al., 2016; Hikabe et al., 2016). This in vitro production of competent mouse oocytes nevertheless did provide a new workbench for studying the adequacy of culture conditions and the timing of specific signaling pathways and for distinguishing essential requirements from helpful but not critical factors. It remains to be seen whether or not a similar investigational tool will be developed for species in which folliculogenesis is a much longer process and the gamete is more dependent on support from neighboring cells. Improving our understanding of intra-follicular communications throughout folliculogenesis will not only bring advances in the science of reproductive biology but should also reveal new physiological targets for the treatment infertility.

Cumulus Cells

Introduction

The somatic cells that directly surround the oocyte are a unique sub-lineage of the granulosa cells, known as “cumulus cells”, that play a unique and critical role providing a niche environment for development of the pluripotent oocyte. The name is derived from a description of their physical appearance in the final stage of folliculogenesis; the periovulatory period, when a burst of mucinous extracellular matrix production (discussed below) gives the cell complex a puffy cumulus cloud-like appearance. The cumulus cells and the oocyte together form a visibly distinguishable complex known collectively as the cumulus oocyte complex or COC; comprising 3 to 4 layers of cumulus cells (totalling around 2000 cells) tightly packed together in concentric layers enveloping the oocyte. The COC becomes apparent in antral follicles where it protrudes into the antrum from the inner granulosa cell layers and is surrounded by follicular fluid. Strong specific interactions among cumulus cells and between cumulus cells and the oocyte mean the COC detaches readily as a discrete intact complex from the granulosa layers and can be isolated by simply aspirating the antral fluid, as is the standard method of collecting oocytes for in vitro fertilization procedures.

Origin of Cumulus Cells

Cumulus and granulosa cells have a shared origin, but are separate sub-lineages. The cumulus are clearly a distinct cell type since they have different functions, hormone responsiveness and fate to the granulosa cells. In fact granulosa cells can be divided into three sub-lineages based on distinctions in hormone responsiveness and gene expression: 1. Mural granulosa cells, which line the follicle wall and usually have some contact with the follicular basement membrane. 2. Antral granulosa cells, which line the antral cavity and contact the follicular fluid; and 3. cumulus cells, which have direct contact with the oocyte through cellular projections that traverse the zona pellucida and form gap junction connections with the oocyte plasma membrane (Winterhager and Kidder, 2015). The cumulus lineage is specified by the actions of oocyte-secreted morphogens Growth and Differentiation Factor 9 (GDF9) and Bone Morphogenetic Protein 15 (BMP15). These two oocyte-specific growth factors induce the cumulus gene expression profile, which includes suppression of luteinizing hormone receptor and progesterone receptor expression preventing the cumulus cells responding to key endocrine stimuli of granulosa cells (Elvin et al., 1999; Eppig et al., 1997). Meanwhile GDF9 and BMP15 signals activate the expression of key cumulus-specific genes; such as glycolysis enzymes (Sugiura et al., 2007) and cholesterol synthetic pathway enzymes (Su et al., 2008) that are essential mediators of healthy oocyte function. The importance of oocyte secreted growth factors in specifying cumulus phenotype is illustrated by the fact that when mural granulosa cells are treated in vitro with these factors, they respond by adopting the cumulus cell gene expression profile (Peng et al., 2013). Furthermore, the cumulus cells adopt a more granulosa like gene expression profile, including increased LH-receptor and steroidogenic enzyme expression, after ovulation when they have become separated from the oocyte (Chaffin et al., 2012). Thus cumulus specification is principally a function of exposure to these oocyte secreted factors through close proximity to the oocyte. The first divergence between cumulus and granulosa cell fates arises due to the formation of the antrum (Eppig et al., 1997), when mural granulosa cells differentiate because they become separated from oocyte derived signals by the antral space and follicular fluid. It is often assumed that the granulosa cell phenotype is the default prior to antrum formation. However, the divergence of the two cell types at antrum formation is synchronous with an increase in LH-receptor expression and increased aromatase expression (Brown et al., 2010b) as the granulosa compartment first emerges as an endocrine organ. The somatic cells of follicles prior to antrum formation have more in common with cumulus cells than granulosa cells, considering that oocytes produce GDF9 and BMP15 from the earliest stages of follicle growth, that close proximity to the oocyte promotes cumulus phenotype and that oocytes require the supportive functions of cumulus cells for their growth and survival. The role of the fluid-filled follicular antrum is an enduring unknown, but this important divergence of somatic cell phenotypes into separate endocrine and oocyte support functions is one clearly important outcome of antrum development.

Cumulus Cell Functions

Metabolic and Nutritional Support of the Oocyte

An intimate association with cumulus cells is essential for oocyte survival and healthy development. Even in the final hours of maturation, dissociation of the cumulus vestment from the oocyte severely impacts oocyte competence (Zhang et al., 2012). The cumulus cells directly contact the oocyte through long transzonal projections with terminal gap junctions connecting cumulus cells to the oocyte (Winterhager and Kidder, 2015). These gap junctions allow transit of small (~1 kDa) molecules between the oocyte and cumulus cell cytoplasm (Edry et al., 2006; Sela-Abramovich et al., 2006). That small cytoplasmic contents are shared between cumulus cells and the oocyte is demonstrated when fluorescent dyes are injected into one cell type but then become rapidly visible in both (Li et al., 2007; Veitch et al., 2004). Endogenous molecules that are transported from the cumulus cells into oocytes include

metabolites of glucose; lactate and pyruvate, ATP, cAMP and cGMP. Transit of glucose metabolites is important as oocytes cannot independently metabolize glucose and they depend on cumulus cells to perform glycolysis and transfer the products intercellularly for energy production in the oocyte mitochondria (Johnson et al., 2007). The cyclic nucleotides cAMP and cGMP are important regulators of oocyte meiotic arrest and their supply from the somatic cells (cumulus as well as granulosa) into the oocyte is a critical means by which the status of the somatic compartments control germ cell maturation (Russell et al., 2016). During its growth the oocyte must accumulate large RNA stores that mediate the early stages of embryogenesis post fertilization, and some evidence exists to suggest that RNA is passed to the oocyte from cumulus cells (Macaulay et al., 2016), but this role is not definitively proven. On the other hand, it is less certain what, if any, endogenous molecules are directly transported from oocyte to cumulus cytoplasm through the gap junctions, although small molecule dyes do flux readily in that direction. The cumulus cells also provide protection for the oocyte from damage caused by elevated reactive oxygen species through transfer of antioxidant reduced glutathione through Gap junctions (Ozawa et al., 2010). In humans the capacity of cumulus cells to produce glutathione is positively associated with oocyte developmental potential (Ceko et al., 2015).

Control of Oocyte Meiosis

The cumulus cells and granulosa cells play a critical role in controlling oocyte progression through meiosis. The oocyte will exit meiotic arrest upon activation of meiosis promoting factor (MPF) a complex of cell cycle proteins that are kept switched off through phosphorylation by protein kinase-A, activated by high cAMP. Cumulus and granulosa cells maintain high oocyte cAMP levels through the transport of cAMP through the gap junctions and cGMP which inhibits cAMP degrading phosphodiesterases in the oocyte, thus keeping oocytes in meiotic arrest. Separation of the oocyte from its cumulus vestment thus results in spontaneous meiotic resumption due to the loss of cAMP and cGMP transport. Once ovulation is triggered, oocytes re-enter meiosis due to closure of the gap junctions and separation of cumulus cells from the oocyte due to cumulus matrix expansion (see below) which lead to reduced cAMP in the oocyte releasing the block on MPF action.

Ovulation

In addition to provision of metabolism and nutrients to the oocyte, the cumulus cells also play a unique and critical role mediating ovulation of the oocyte. Ovulation is triggered by a surge of Luteinizing Hormone from the pituitary gland. This high level of LH acts on granulosa and theca cells of the follicle, but not cumulus cells because the action of GDF9 and BMP15 from the oocyte represses expression of the *Lhcgr* gene, and hence cumulus cells lack LH receptors and remain unresponsive (Eppig et al., 1997). Cumulus cells, like granulosa cells, do have FSH receptors and thus likely sense the smaller surge in FSH from the pituitary at the beginning of ovulation. But granulosa cells principally transmit the ovulatory signal to cumulus cells by activating the production of EGF-like Ligand (EGF-L) genes; *Areg*, *Ereg* and *Btc* and these factors strongly influence cumulus cells in the periovulatory period (Park et al., 2004). FSH and EGF-L promote very large, rapid production of a unique ECM in the COC. The glycosaminoglycan hyaluronan (HA) is synthesized via strong induction of hyaluronan synthase 2 gene (*Has2*) as well as glycolytic genes necessary to synthesize the HA components from glucose (Sugimura et al., 2015). The very long HA molecules are cross-linked by an HA-binding protein complex of TSG6 and PTX3 also rapidly and simultaneously made by the cumulus cells (Russell and Robker, 2007). Expression of *Has2*, *Tnfrsf10b* and *Ptx3* genes requires the presence of oocyte-secreted signals GDF9 and BMP15 which specify the cumulus phenotype but cannot activate the ovulatory gene induction. Expression of each of these cumulus cell genes is essential for ovulation and additionally some proteins synthesized by the granulosa cells that are incorporated into the COC matrix are also necessary for normal ovulation. Specifically, versican a large HA-binding proteoglycan and ADAMTS1 a proteoglycanase enzyme that processes versican are incorporated in the HA matrix of the COC (Brown et al., 2010a), and are important for normal ovulation, but are both synthesized in the GC in response to the LH surge. Some blood borne proteins are also incorporated and play key roles in the COC matrix, including liver derived inter-alpha trypsin inhibitor (*IαI*) and fetuin B (Dietzel et al., 2013; Zhu et al., 2008). Combined, the findings that each individual component of the COC matrix is essential for ovulation to succeed demonstrates that the COC matrix is a key mediator of ovulation. The fact that oocyte factors promote the synthesis of this matrix provides a mechanism whereby oocytes can 'guide' the ovulation process and hence ovulation may be considered a "checkpoint" event that ensures the release of only high quality oocytes, i.e. ones that can sustain the appropriate responsiveness in the cumulus cells.

Oocyte Developmental Competence

The role of cumulus cells in establishing oocyte developmental competence is supported by growing cumulative evidence. As the cumulus complex provides metabolic and nutritional support for the developing oocyte, removal of the cumulus vestment results in slow starvation and death of the oocyte. Even when cumulus cells are removed acutely in the final stages of maturation, the competence of oocytes to fertilize and develop normally into embryos is severely compromised. The importance of cumulus gene expression for health of the oocyte is demonstrated by a range of studies showing that the expression level of key cumulus genes is directly associated with the developmental outcomes for that oocyte. Genes whose expression is positively correlated with high quality oocyte outcomes include *Has2*, *Grem1*, *Tnfrsf10b*, *Ptx3*, *Glut4*, *Vcan*, and several others (Mckenzie et al., 2004; Anderson et al., 2009; Assou et al., 2008; Gebhardt et al., 2011; Wathlet et al., 2012). Thus acquisition of oocyte developmental competence is a bi-directional mechanism whereby oocyte-derived signals act on cumulus cells to promote expression of genes and pathways

required to support oocyte growth; and the cumulus cells in turn feedback the reciprocal trophic support. Cumulus cells and the COC matrix also play important roles after ovulation in the interaction of the COC with the fallopian tube (or oviduct) epithelial cells. Adhesive interactions between the cumulus and fallopian epithelial cells mediates the collection of the oocyte and its transport through this long tube to meet the sperm and be fertilized (Lam et al., 2000).

Fertilization

Contact with the COC matrix signals to the sperm that they are near their final target and sperm are intricately influenced by the cumulus cells and matrix which induce the final maturation phases in the sperm; capacitation and the acrosome reaction, making them competent for fertilization. The acrosome reaction in sperm is promoted upon contact with the COC which maximizes sperm's potential to fertilize the oocyte upon reaching the zona pellucida (Hong et al., 2009; Jin et al., 2011).

As well as being important for ovulation, the composition of the COC matrix is also critical for fertilization. Mutant mouse models with ablation of each of the cumulus matrix proteins uniformly show deficiencies in ability to become fertilized, due to changes in matrix stiffness, specific protein interactions between the COC and sperm as well as possible reduction in oocyte competence (Russell and Robker, 2007). Protease inhibitors I α I and Fetuin B in the COC matrix and prevent premature hardening of the zona pellucida which must occur only after fertilization as it prevents sperm binding (Dietzel et al., 2017; Dietzel et al., 2013). The matrix is also capable of excluding certain molecules including glucose, while sequestering and concentrating cumulus secreted factors such as prostaglandins –and most likely oocyte secreted factors also (Dunning et al., 2007). This process may intensify the signaling actions of these factors prolonging their action and possibly leading to concentration dependent changes in the response both of cumulus cells and sperm. Post-ovulation the cumulus cells steroidogenic activity (Vanderhyden and Tonary, 1995) increases and high concentrations of progesterone are known to promote the sperm acrosome reaction, hyperactivation of sperm motility and guidance of hyperactivated sperm towards the oocyte (Unates et al., 2014). The abundant hyaluronan making up the bulk of the COC matrix is digested by a specific hyaluronidase enzyme expressed on the sperm head to facilitate sperm penetration. The matrix also presents a barrier which selects sperm by preventing the penetration of any individual sperm with defective hyaluronidase or motile activity. This has been illustrated by showing that using COC matrix penetration as a laboratory method to select sperm used in IVF is an effective way to enrich high quality sperm (Hong et al., 2009). The digested hyaluronan fragments interact with Toll-like receptors (TLR) on the cumulus cells leading to production of cytokines, chemokines and prostaglandins which accumulate after fertilization and trigger further degradation of the COC matrix mediated by the cumulus cells (Tamba et al., 2010). Importantly chemokines secreted by the cumulus cells, activate receptors on the sperm mid-piece to enhance successful fertilization (Caballero-Campo et al., 2014).

Glossary

Anti-Müllerian hormone (AMH) A growth factor secreted by Sertoli cells to induce the degeneration of the Müllerian ducts in male embryos.

Coelomic epithelium Mesothelium derived from the splanchnopleura of lateral plate mesoderm that forms the lining of the organs in the coelomic cavity.

Folliculogenesis The growth, development, and maturation of an ovarian follicle.

Genital/gonadal ridge The anlagen of the testis in males and the ovary in females.

Germ cells Cells whose descendants become either sperm or egg.

Granulosa cells Ovary-specific cells that produce estrogen and progesterone, and support female germ cells throughout oogenesis.

Leydig cells The steroidogenic cells of the testis that synthesize testosterone.

Mesonephroi A pair of kidney-like organs derived from the intermediate mesoderm that function temporarily in the embryo, and from which the male and female reproductive tract are derived.

Oogonia Ovarian germ cells derived from PGCs that give rise to primary oocytes.

Primordial germ cell (PGC) Germ cell stage preceding sex differentiation.

Sertoli cells Testis-specific cells that secrete AMH in the developing embryo, and function to support male germ cells throughout spermatogenesis.

Sex-determining region Y (Sry) Gene encoding a transcription factor that initiates male sex determination; also known as testis determining factor (TDF).

Theca cells Endocrine cells associated with ovarian follicles that produce the androgen substrate for estrogen biosynthesis.

Introduction

Mammalian embryonic gonads initially form as a bipotential primordium that is morphologically indistinguishable in male and female embryos. A chromosomally determined sexual fate decision elicits the activation of the testis-specific or the ovary-specific pathway, and initiates the transformation of the common primordial gonads into either the male or female phenotype. The differentiated ovary produces and maintains a pool of oocytes, of which a subset is ovulated for fertilization. Additionally, the ovary functions as an endocrine organ, synthesizing and secreting the steroid hormones estrogen and progesterone that stimulate the development of secondary sex characteristics and prepare the accessory reproductive organs to facilitate pregnancy, birth, and lactation. Consequently, organogenesis of the ovaries is a highly important process for female fertility and reproductive success. Defects during gonad formation and development are pertinent to disorders of sex development (DSDs), and may also contribute to infertility or ovarian cancer. Knowledge of the process of gonadogenesis is therefore crucial to our understanding of reproductive pathologies, and may inform new treatment approaches for associated abnormalities. This article provides an overview of the key events that occur during the formation of the bipotential primordial gonad and the differentiation of the ovary, with particular focus on organogenesis of the ovary in mice, the most extensively studied mammalian model, and in humans.

The Urogenital System

Early in mammalian gestation, the embryo becomes trilaminar as it undergoes gastrulation to form three germ layers: the ectoderm, mesoderm, and endoderm. All embryonic tissues and organs are derived from these germ layers as the cells proliferate, migrate, and differentiate. The mesodermal layer is regionalized into the paraxial, intermediate, and lateral plate mesoderm. The intermediate mesoderm forms the urogenital system which includes the gonads and kidneys, as well as their associated duct systems. The urogenital ridges form bilaterally as longitudinal mesodermal elevations in the dorsal body wall of the embryo. Three sets of kidneys—the pronephroi (transitory and non-functional), mesonephroi (interim kidneys), and the metanephroi (becomes the permanent

kidneys)—develop from the urogenital ridges. Formation of the gonads is concurrent and closely associated with the differentiation of the mesonephroi. Invaginations of the surface epithelium of the mesonephroi give rise to the mesonephric (Wolffian) ducts and the paramesonephric (Müllerian) ducts. In male embryos, the testes produce testosterone which influences the differentiation of the Wolffian ducts to form the internal male genitalia, such as the vas deferens, epididymis, and the seminal vesicle. Additionally, the male gonad produces Müllerian-inhibiting substance (MIS), also known as anti-Müllerian hormone (AMH), which induces the degeneration of the Müllerian ducts. In contrast, the developing female gonad lacks these factors and the Müllerian ducts give rise to the fallopian tubes (oviducts), the uterus, the cervix, and the cranial portion of the vagina while the Wolffian ducts degenerate. Recent evidence suggests that the transcription factor, COUP-TFII, suppresses signaling that is required to maintain the Wolffian ducts and therefore actively regulates differentiation of the female reproductive tract (Zhao et al., 2017).

Formation of the Bipotential Gonad: The Indifferent Stage of Sexual Development

Gonadogenesis begins with the formation of the genital (gonadal) ridges which are the somatic precursor structures of both the testis and ovaries. The genital ridges form as a bulge or outgrowth of the coelomic epithelium on the ventromedial side of the mesonephroi by the fifth week of gestation in humans, and by embryonic day 10 (E10) in mice (Satoh, 1991; Waldeyer, 1870; Kaufman, 1992; Byskov, 1986). This proliferation of the coelomic epithelium and the underlying mesenchyme produces the somatic constituents of the gonads. There are at least two distinct bipotential somatic precursor lineages: (1) supporting cell precursors that differentiate into Sertoli cells in the testis or granulosa cells in the ovary, and (2) steroidogenic progenitors that produce Leydig cells in the testis or theca cells in the ovary (Karl and Capel, 1998; Schmahl et al., 2000). Stromal cells which are not specialized between sexes are also present at the genital ridge, and are responsible for structural patterning and angiogenic vascularization of the gonad. Genital ridge formation is therefore an indispensable prerequisite for development of both testis and ovaries, which remain bipotential at this stage until an intricate network of cellular signals begins to drive sexual differentiation.

Genetic Regulation of Gonad Formation

Several transcription factors and signaling proteins perform crucial regulatory roles in the development of the bipotential gonad. These were recently reviewed (Eggers et al., 2014; Tanaka and Nishinakamura, 2014), and are summarized here (also see Table 1). Steroidogenic factor 1 (*Sf1*), also known as *Nr5a1*, encodes an orphan nuclear hormone receptor that is expressed in both the gonad and steroidogenic tissues such as the adrenal glands (Lu and Yamashita, 2017). *Sf1* null mice exhibit agenesis of the gonads and the adrenal glands. *Sf1* is also an important regulator of *Sox9*, an essential gene for mediating testis differentiation. The Wilms tumor gene (*Wt1*) encodes a zinc finger transcription factor that is involved in the regulation of early gonad development, and differentiation of the testis (Kreidberg et al., 1993). *Wt1* null mice fail to undergo gonadogenesis, and their kidneys do not develop. Additionally, the *Wt1* protein has two isoforms, one lacking and one containing a KTS (lysine, threonine, and serine) amino acid motif. Mice lacking the *Wt1*(+KTS) isoform lose the ability to upregulate the testis-determining gene *Sry*, and exhibit male-to-female sex reversal. The *Wt1*(−KTS) isoform, in conjunction with *Lhx9*, directly activates the *Sf1* gene promoter and regulates the expression of testis-inducing factors such as *Amh*. This isoform is also important for the maintenance of the gonadal primordium. In humans, *WT1* mutations are also implicated in a form of kidney cancer that primarily affects children. *Lhx9* encodes the Lim/homeobox 9 protein which is another regulator of *Sf1* (Birk et al., 2000). *Lhx9* null mice also fail to undergo gonadogenesis. A deficiency in *Lhx9* contributes to the loss of *Amh* and testosterone, which causes XY mice to develop as females.

Table 1 Genes involved in mouse gonad formation

Gene	Protein/Function	Mutant phenotype	References
<i>Cbx2</i>	Chromobox, chromatin modification and remodeling factor	Impaired ovary development, male to female sex reversal.	Katoh-Fukui et al. (1998)
<i>Emx2</i>	Homeobox transcription factor	Lack kidney, uterine, gonad, reproductive tract.	Miyamoto et al. (1997)
<i>Gata4</i>	Zinc finger transcription factor	Inhibition of genital ridge formation.	Hu et al. (2013)
<i>Igfr1</i>	Insulin like growth factor receptor	Decreased proliferation of somatic progenitor cells.	Nef et al. (2003)
<i>Insr</i>	Insulin receptor	Decreased proliferation of somatic progenitor cells.	Nef et al. (2003)
<i>Lhx9</i>	Lim homeobox	Impaired gonadogenesis	Birk et al. (2000)
<i>Sf1</i>	Steroidogenic factor, orphan nuclear hormone receptor	No gonads or adrenal glands	Lu and Yamashita (2017)
<i>Six1/4</i>	Six family homeobox	Double knockouts have smaller gonads.	Kawakami et al. (2000)
<i>Wt1</i>	Zn finger transcription factor	No gonad development.	Kreidberg et al. (1993)

Empty spiracles homeobox 2 (Emx2) encodes a homeobox transcription factor involved in urogenital development (Miyamoto et al., 1997). *Emx2* null mice fail to develop kidneys, ureters, gonads, and genital tracts. Cellular polarity is also lost in the forming gonadal ridges of *Emx2* null mice leading to the abnormal assembly of tight junctions. Two other homeobox containing genes, *Six1* and *Six4*, are mammalian homologs of the *sine oculis homeobox (Six)* family in *Drosophila* (Kawakami et al., 2000). Both function redundantly in mouse embryogenesis. *Six1* and *Six4* double-mutant mouse embryos exhibit decreased gonad size in both sexes and abnormal differentiation of the testis in XY gonads.

The chromobox homolog 2 protein encoded by the *Cbx2* gene is a chromatin modification and remodeling factor that is involved in early gonadal development (Katoh-Fukui et al., 1998). *Cbx2* has been shown to upregulate *Sf1*, *Wt1*, and *Sry*. Deletion of *Cbx2* leads to impaired development of the ovary in XX mouse models, and male-to-female sex reversal in XY mice. *Cbx2* null mice appear to have normal development of the coelomic epithelium, but the gonadal cells later exhibit defective proliferation.

The GATA-binding protein 4 (*Gata4*) is a zinc finger transcription factor whose deletion is lethal to mouse embryos prior to genital ridge formation (Hu et al., 2013). Conditional knockdown of *Gata4* expression in mouse embryos after E8.75 causes the coelomic epithelium to remain as a morphologically undifferentiated monolayer, thereby preventing genital ridge formation. The insulin/insulin-like growth factor (IGF) signaling pathway is another crucial regulator of gonadogenesis (Nef et al., 2003). Mouse embryos without the insulin receptor (*Insr*) and the IGF receptor (*Igfr1*) have decreased proliferation of somatic progenitor cells in the gonads of both genotypic sexes prior to gonadal sex determination, and the testis fail to develop. Loss of insulin/IGF signaling can induce male-to-female sex reversal, and is also associated with reduced *Sry* expression levels. Proper spatiotemporal expression of each of these genes is imperative for establishing the somatic gonad.

Sex Determination

In mammals, dimorphic sex determination and differentiation progresses in three distinct phases. Firstly, the genetic sex of the embryo is determined at fertilization by the chromosomal complement of the zygote. Females are normally endowed with two X chromosomes, while males have an X and a Y sex chromosome. This genetic information facilitates gonadal sex determination during the second phase, by triggering growth of the bipotential gonad towards a testicular or ovarian fate. The short arm of the Y chromosome contains the gene encoding the mammalian testis-determining factor (TDF) known as *Sry* (sex-determining region Y). The spatiotemporal expression pattern of *Sry* is strictly controlled, and is first detected in the mouse gonad around E11, peaking at E11.5, before disappearing after E12.5 (Tanaka and Nishinakamura, 2014). *Sry* upregulates *Sox9*, and is both necessary and sufficient to direct the indifferent gonad towards the male phenotype in mice and humans (Koopman et al., 1991; Sinclair et al., 1990). *Sry* induces testicular morphogenesis by coordinating the differentiation of Sertoli cells and other testis-specific lineages. The presumptive ovarian equivalent of *Sry* has not yet been identified, and there is no evidence of a specific ovary determining factor. However, the ovary differentiation pathway is activated in the absence of functional *Sry* protein, and is primarily driven by the WNT/ β -catenin signaling pathway. Accordingly, although initial morphogenesis of the gonad is macroscopically similar between sexes, the gonadal transcriptome is notably different. The third stage, phenotypic sex determination, begins perinatally and continues throughout sexual maturation as the endocrine products of the gonads stimulate the development of secondary sex characteristics. Mutations or defects that compromise development during any of these three stages could lead to urogenital abnormalities or sex reversal.

The Ovary Differentiation Pathway

Differentiation of the bipotential gonads to the ovaries is not simply a passive process that occurs if there is no *Sry*. There are several ovary specific genes and signaling pathways that elicit female gonadal determination and development and this gonadal fate requires active repression of the testis pathway (Eggers et al., 2014; Chassot et al., 2014) (see Table 2). *Foxl2* encodes the forkhead box L2 transcription factor and is upregulated in the developing ovary (Uhlenhaut et al., 2009). Mutations of this gene in humans lead to blepharophimosis ptosis epicanthus inversus syndrome (BPES), which is characterized by eyelid malformation as well as, in some cases, primary ovarian insufficiency. Conditional knockdown of the *Foxl2* gene causes granulosa cells to become reprogrammed into Sertoli cells.

Table 2 Genes involved in mouse ovary differentiation

Gene	Protein/function	Mutant phenotype	References
<i>Ctnnb1</i>	β -catenin, Wnt signaling pathway	Ectopic expression causes male to female sex reversal.	Liu et al. (2009)
<i>Foxl2</i>	forkhead box transcription factor	Female to male sex reversal of somatic cells	Uhlenhaut et al. (2009)
<i>Fst</i>	Follistatin, activin antagonist	Mutants have female to male sex reversal.	Yao et al. (2004)
<i>Rspo1</i>	R-spondin homolog 1	Mutants have female to male sex reversal	Chassot et al. (2008)
<i>Wnt4</i>	Wnt signaling	Decreased proliferation of somatic progenitor cells.	Tomizuka et al. (2008)

β -Catenin, also known as Catenin beta-1 (Ctnnb1), transcriptionally regulates a variety of genes including *Wnt4* and *Fst* which are important for ovarian development (Liu et al., 2009). Ectopic expression of β -catenin in the developing XY mouse gonad causes male-to-female sex reversal, but the mechanism driving this trans-differentiation is unclear. WNT family members are conserved secreted proteins with roles in various biological processes. WNT3A participates in the stabilization of β -catenin and allows it to transcribe its target genes. WNT4 is known to activate canonical WNT signaling during gonadal development (Tomizuka et al., 2008). Females with heterozygous missense *WNT4* mutations exhibit agenesis of the reproductive tract, while *Wnt4* in the mouse is also important for gonadal morphogenesis via its role in sex determination and female development.

RSPO proteins activate the WNT/ β -catenin signaling pathway by binding to the LGR4, LGR5, and LGR6 G protein-coupled receptors, or by binding to ZNRF3 and RNF43 which are negative-feedback regulators of WNT signaling (Chassot et al., 2008). Disruption of human *RSPO1* can lead to female-to-male sex reversal, suggesting that it plays a crucial role in sex determination and female differentiation. At E12.5 in the mouse *Rspo1* and *Wnt4* become expressed in an ovary specific manner, and their gene products are secreted by the somatic cells of the ovary. *Rspo1* null mice exhibit sex reversal, bearing ovotestes. The *Rspo1*^{-/-} embryo demonstrates abnormalities in the XX gonad such as the presence of testis-like vasculature, and reduced germ cell proliferation. Similarly, a deficiency in *Wnt4* is associated with inducing male-like vascularization of the gonad in XX embryos. There is also evidence suggesting that *Wnt4* functions as a survival factor in female germ cells, as there are nearly three times as many apoptotic germ cells in the *Wnt4* deficient gonad, when compared to wild type gonads.

Follistatin (*Fst*) expression is stimulated by *Wnt4* in the XX gonad from E11.5 onwards, but is not expressed in the XY gonad (Yao et al., 2004). *Fst* encodes an activin-binding protein that antagonizes Activin B. This inhibitory action prevents male-like vascularization of the gonad. Subsequent development of the differentiated ovary will involve the production and development of the ovarian follicles.

Primordial Germ Cells: The Embryonic Precursors of Gametes

Primordial germ cells (PGCs) colonize the bipotential gonad in association with the somatic cells, and differentiate to produce haploid eggs or sperm. During gastrulation in mice, at around E7, inductive cell-cell interactions establish the germ line by specifying the allocation of PGCs. The genetic basis for germ cell specification is thought to involve the expression of the *fragilis* and *stella* genes in PGC founder cell lineages, allowing them to retain pluripotency while neighboring cells acquire a mesodermal fate (Saitou et al., 2002). Intercellular signaling involving Bone Morphogenetic Protein 4 (*Bmp4*) is also critical for initiating the formation of the germ line. *Bmp4* null mouse embryos lack PGCs and an allantois which are both derived from the proximal epiblast (Lawson et al., 1999). The *Bmp* signaling pathway regulates the expression of two key genes that are essential for germ cell fate: PR domain containing protein 1 (*Prdm1*) which acts to repress the somatic cell fate, and PR domain containing protein 14 (*Prdm14*) which transcriptionally regulates germ cell pluripotency and epigenetic reprogramming (Windley and Wilhelm, 2015).

PGCs migrate via the hindgut and the dorsal mesentery to the developing gonadal ridges from approximately E9.5 to E11.5 in the mouse and from the fifth to seventh week of gestation in humans (Clark and Eddy, 1975; Fujimoto et al., 1977). During this time, the number of PGCs increases from approximately 40 to 250 in mice, and from approximately 100 to 5000 in humans (Cummings and Kavlock, 2004; Saitou and Yamaji, 2012). The PGCs rapidly proliferate by mitosis and increase in number to colonize the developing gonads as oogonia or spermatogonia. This proliferation produces a maximum of almost 7 million germ cells by the 5th month of gestation in humans, and around 25,000 germ cells by E13.5 in mice. At E11.5 in the mouse embryo and in the seventh to ninth week of gestation in humans, PGCs display similar expression patterns of germline and pluripotency genes. These germ cell specific genes include *BLIMP1*, *AP2 γ* , *UTF1*, *DAZL*, *Kit*, and *DDX4*, while the pluripotency genes include *OCT4*, *NANOG*, *PRDM14*, and *LIN28* (Dolci et al., 2015). The KIT receptor and its ligand KITL, are well known for promoting cell survival and proliferation during gametogenesis. Loss of KIT function impairs PGC proliferation and migration, results in ectopic PGCs, and affects the growth of early ovarian follicles (Buehr et al., 1993; Huang et al., 1993; McCoshen and McCallion, 1975; Mintz and Russell, 1957). By E13.5 in mice and by the tenth week of gestation in humans, oogonia begin to enter meiosis and are called oocytes. Developing oocytes arrest in the diplotene stage of the first meiotic prophase until ovulation begins during puberty, while spermatogonia enter a state of quiescence and reinitiate development at the onset of puberty.

Development of the Ovaries

The differentiated ovary displays notable complexity in structure and function, and is histologically identifiable around the twelfth week of gestation in humans and E13.5 in mice, by the presence of loose cordlike structures termed ovigerous cords (Loffler and Koopman, 2002; Odor and Blandau, 1969). Ovigerous cords consist of clusters of primordial germ cells that are surrounded by somatic cells. Ovarian PGCs in these clusters are physically interconnected by cytoplasmic bridges, and develop synchronously as germ cell cysts (Pepling and Spradling, 1998). Cysts subsequently undergo programmed breakdown to form primordial follicles, consisting of an individual germ cell or oocyte surrounded by a monolayer of somatic granulosa cells (Pepling and Spradling,

2001). Somatic cells extend thin cytoplasmic prolongations between germ cells in ovigerous cords, thereby facilitating cyst breakdown and follicle assembly (Odor and Blandau, 1969; Pepling and Spradling, 2001). The features of early oocyte development are very similar in mice and humans, with the main difference being that cyst breakdown and primordial follicle formation occur perinatally in the mouse, but before birth in humans (Sarraj and Drummond, 2012).

Cellular and Structural Aspects of Fetal Ovarian Differentiation

Contrary to other organs in the embryo, embryonic gonads are unique for their capacity to become two morphologically distinct organs: testes or ovaries. In mammals, the decision of embryonic gonads to develop into testes or ovaries relies on the sex chromosomes and the presence or absence of the sex-determining gene of the Y chromosome or SRY. As a consequence, embryonic gonads undergo dimorphic cellular and morphological changes that are specific for either the testis or the ovary. While sex determination of the testis results in radical changes in the morphology of the embryonic gonads, sex determination of the ovary yields subtle changes. This article focuses on the cellular and morphological changes that transform undifferentiated embryonic gonad into an ovary.

Sex Determination of the Ovary: Cellular Changes

Long before the undifferentiated gonads acquire the characteristic structures of an ovary, they already contain precursor cell populations that serve as the foundation of the ovary. Through a process called cell differentiation, these cell populations change their cellular characteristics to become specialized cell types specific for the testis or the ovary. When the undifferentiated gonads transform into ovaries, major cellular events occur in three cell populations: (1) the supporting cells, a subtype of somatic cells that become granulosa cells, (2) the steroidogenic cell precursors, another subtype of somatic cells that later become theca cells, and (3) the primordial germ cells, which become oocytes through the process called oogenesis.

Origins and Differentiation of the Somatic Cells in the Ovary

Supporting Cells or Granulosa Cells

Among the somatic cells in the undifferentiated gonads, supporting cells play the most critical role in sex determination. This is the first cell population that chooses its fate, and differentiates into cell types that are specific to the sex of the embryo: Sertoli cells in the testis or granulosa cells in the ovary. Sertoli and granulosa cells derive from a common precursor population that arises from the coelomic epithelium on the surface of the undifferentiated gonads (Karl and Capel, 1998; Albrecht and Eicher, 2001). The precursor cells contribute to the thickening of the gonads by expanding their population and then entering the gonads. Sex determination of these cells relies on their sex chromosome constitution, particularly the Y-chromosome-linked SRY gene. In the presence of SRY, the supporting cell progenitors become Sertoli cells whereas in the absence of SRY, supporting cell progenitors develop into granulosa cells, marking the first event of ovary sex determination.

Studies in rodents and larger mammals suggest that granulosa cell population does not solely arise from the common supporting cell progenitors at the time of sex determination (Mork et al., 2012; Rastetter et al., 2014; Smith et al., 2014). In fact, granulosa cell populations could derive from at least two distinct sources at different stages of development (Fig. 1):

- The first wave of development corresponds to the appearance of the above-mentioned population of supporting cell precursors, which give rise to the first cohort of granulosa cells at the time of sex determination. In female embryos, this recruitment of

Fig. 1 *Origins of the granulosa cells.* Two waves of cell differentiation give rise to the granulosa cells. The first population of granulosa cells originates from the coelomic epithelium at the onset of ovary sex determination, and gives rise to the granulosa cells located in the medulla of the ovary. The second population of granulosa cells originates from the ovarian surface epithelium of the neonatal ovary, and gives rise to the granulosa cells of the cortex. This model is based on the findings by Mork et al. (2012).

supporting cell precursors from the coelomic epithelium continues for a short time after sex determination. These granulosa cells remain mostly located at the innermost part of the ovary, called medulla. This first cohort of granulosa cells later participates in the formation of the first wave of follicles in the medulla of the ovary.

- The second wave of granulosa cell differentiation appears late in gestation. Similar to the first wave, granulosa cells from the second wave of development arise from the ovarian surface epithelium. The cell recruitment from the surface epithelium is continuous from fetal to early postnatal stage, concomitant with the initiation of follicle assembly. The second cohorts of granulosa cells remain close to the surface epithelium, contributing to the growth of this region called cortex. These granulosa cells participate in the formation of the second wave of follicles in the cortex of the ovary and give rise to the majority of adult granulosa cells (Zheng et al., 2014).

Contrary to Sertoli cells in the fetal testis that proliferate during the course of sex determination, fetal granulosa cells cease proliferation once their fate is determined. As the fetal ovary develops, granulosa cell population expands through the cell recruitment from the ovarian epithelium surface. Proliferation of granulosa cells only resumes after folliculogenesis is initiated. Establishment of the supporting granulosa cell populations is the first step of ovary sex determination, and it influences the appearance of other somatic cell populations in the embryonic ovary.

Steroidogenic Cells or Theca Cells

In addition to the supporting cells, steroidogenic cells are another somatic cell population that plays a critical role in ovarian physiology. Both testes and ovaries contain a population of steroidogenic cells that contributes to the production of sex steroids. In the ovary, these steroidogenic cells are called theca cells. Leydig cells, the testis counterpart of theca cells, differentiate and become steroidogenically active soon after testis sex determination. The timing of theca cell differentiation in the ovary, on the other hand, varies among species. For instance, theca cells in the mouse become distinguishable after birth, when the follicles are assembling (Mannan and O'Shaughnessy, 1991). In larger mammals, theca cells differentiate during embryonic development of the ovary. Similar to the testicular Leydig cells, the ovarian theca cells arise from non-steroidogenic precursor cells of two distinctive fetal origins (Liu et al., 2015):

- The majority of the theca cells originate from the coelomic epithelium of the embryonic ovary. After the coelomic epithelium has given rise to the supporting cell precursors, some cells from the coelomic epithelium ingress into the embryonic ovary to become mesenchymal cells of the ovarian stroma (Karl and Capel, 1998). Then, after ovarian differentiation is established, some of these mesenchymal cells differentiate into theca cells in response to signals coming from neighboring granulosa cells and oocytes.
- In addition to the mesenchymal cells in the fetal ovary, a subset of theca cells has an extragonadal origin: they come from the mesonephros connected to the ovary. In the mouse, the theca cell precursors in the mesonephros migrate into the ovary around birth, right before steroidogenic theca cells are detected. As the theca cells differentiate, their populations expand and begin to surround primary follicles, which are composed of a single oocyte enclosed in a layer of granulosa cells.

Establishment of the Germ Cells in the Ovary

Oocytes in the ovary and sperm in the testis both arise from the same embryonic cell population: the primordial germ cells. Primordial germ cells are formed early during embryogenesis, before the primitive gonads are even established. As the undifferentiated gonads start to form in the embryo, primordial germ cells migrate and colonize the gonads. Contrary to the supporting cells, the sexual fate of germ cells does not directly rely on their sex chromosome content. Instead, sex determination of the germ cells is controlled by signals that they receive from the surrounding gonadal environment, in particular from the supporting cells. If the supporting cells differentiate into ovary-specific granulosa cells, the germ cells commit to a developmental pathway that ultimately lead them to become oocytes. Once sex determination of the ovary is initiated, primordial germ cells (or oogonia) undergo several rounds of synchronous cell division or mitosis. At the end of each cell division, the oogonia are not completely separated: they remain connected between each other through intercellular bridges and form clusters of oogonia known as ovarian germ cell cysts (Pepling and Spradling, 1998) (Fig. 2). Within the cysts, the intercellular bridges allow oogonia to exchange cytoplasmic material. From insects to vertebrates, the formation of ovarian germ cell cysts is highly conserved throughout evolution. Each cyst is initially composed of oogonia that originate from a single founder primordial germ cell. Depending of the species, germ cell cysts can partially fragment and aggregate with other germ cell cysts that arose from another primordial germ cell (Lei and Spradling, 2013).

At the time of ovarian cyst formation, the ovary reaches the highest number of germ cells it will ever contain. Soon after, the oogonia progressively stop proliferating, and begin to condense their chromosomes. This chromosome condensation indicates that female germ cells are initiating meiosis, a unique cellular division process that occurs only in germ cells. Meiosis initiation in the fetal ovary is a key morphological indicator of sex differentiation of the germ cells. In the testis, germ cell meiosis is only initiated at puberty. In the fetal ovary, meiosis initiation occurs in an asynchronous way both spatially and temporally. In mice, meiosis progresses in an anterior-to-posterior wave (Menke et al., 2003; Yao et al., 2003). On the other hand, in human and large mammals, meiosis is established in an inner-to-outer fashion, from the ovarian cortex extending to the region close to the ovarian

Fig. 2 Sex differentiation of the female germ cells. Primordial germ cells migrate into the embryonic ovary before sex determination. Once they colonize the gonad, primordial germ cells (or oogonia) undergo incomplete cell divisions, resulting in the formation of germ cell cysts in which the oogonia remain connected through intercellular bridges. These intercellular bridges allow the oogonia to exchange cytoplasmic materials. The oogonia then initiate meiosis, and their chromosomes start to condense. The female germ cells are now referred as oocytes. In parallel to meiosis initiation, germ cell cysts start to break down. Some oocytes undergo apoptotic cell death whereas the remaining oocytes arrest in late prophase I of meiosis.

surface epithelium. Initiation of meiosis is thought to be controlled by retinoid acids (Bowles et al., 2006). The sources of retinoid acids vary among species from the mesonephros close to the anterior part of the ovary in rodents to the ovary itself in humans and large mammals. As oogonia enter meiosis, they develop into oocytes. While the chromosomes progressively condense, homologous chromosomes pair together and exchange genetic material through a process called crossing-over. During fetal ovary development, oocytes progress up to the late prophase of meiosis I. Once oocytes reach the diplotene stage of prophase I, meiosis is arrested, only to resume after puberty.

In parallel to the event of meiosis initiation, oocytes undergo a progressive loss called attrition, another hallmark of germ cell commitment to female differentiation. In the beginning, soon after meiosis is initiated, the pace of oocyte loss is slow; then, around the time of follicle formation, the loss becomes massive. Oocyte attrition occurs through programmed cell death of two types: apoptosis that is triggered by signals from the oocytes themselves and the neighboring granulosa cells; and autophagy. It remains unclear why the fetal ovary undergoes such a big loss of oocytes. Three hypotheses have been proposed to explain the massive loss of oocytes in the fetal/neonatal ovary:

- First, loss of oocytes may result from an intrinsic quality control checkpoint: oocytes that initiate meiosis improperly, or have an abnormal chromosomal composition/DNA damage, are eliminated whereas healthy oocytes survive.
- Second, within the ovarian germ cell cysts, some oocytes only serve as nursing cells, providing organelles and cytoplasmic material through the intercellular bridges to other oocytes. Loss of organelles such as mitochondria, “the powerhouse” of the cell, results in the death of these nursing cells (Lei and Spradling, 2016).
- Third, extrinsic stimuli could affect germ cell survival/loss: the contact between oocytes and granulosa cells could be necessary for oocyte survival. As a consequence, the oocytes that fail to be surrounded by granulosa cells degenerate. Loss of oocytes balances the ratio between oocytes and granulosa cells in order to allow proper formation of follicles.

Survival of oocytes is based on multiple criteria of selection. Therefore, these three hypotheses are not mutually exclusive, and oocyte death probably results from a combination of these intrinsic and extrinsic mechanisms. Consequently, depending upon the species, up to 90% of the total oocyte population is lost in the fetal or neonatal ovary.

Sex Determination of the Ovary: Morphological Changes

The morphological changes leading to ovarian development depends on the recruitment, structural organization, and communication between the cell populations mentioned in the first part of this article. The undifferentiated gonad is an oblong, streak-like structure undistinguishable between male and female embryos. After the onset of gonadal sex determination, the embryonic ovary progressively becomes thicker in diameter and shorter in length, and ultimately acquires a round shape. The morphological change of fetal ovaries is slow and unremarkable compared to the fast-paced growth of the embryonic testis. As a result, soon after sex determination is initiated, embryonic ovary and testis can be distinguished by their size, with the ovary being significantly smaller than the testis. In addition, while the embryonic testis undergoes dramatic structural reorganization, the structure of the fetal ovary

Fig. 3 Morphological changes in the mouse fetal ovary: from ovigerous cord formation to primordial follicles. In the embryonic ovary, the ovigerous cords are formed by the loose surrounding of germ cell cysts by granulosa cells. As the ovigerous cords form, they are in contact with the surface epithelium, source of granulosa cell precursors, and become delimited from the stroma by a basement membrane. In the neonatal ovary, the germ cell cysts progressively breakdown in a medulla-to-cortex fashion, resulting in smaller ovigerous cords and ultimately to the formation of primordial follicles. Theca cells differentiate from mesenchymal cells originating from both the ovarian stroma and the mesonephros (arrows).

initially remains similar to that of the undifferentiated gonads, with somatic and germ cells mixed throughout the gonad. From the time of ovary sex determination in fetal life to folliculogenesis in adulthood, granulosa cells and female germ cells form a tight cellular and structural connection. Their capacity to interact is critical for their cellular development, as well as for their ability to form particular structures, from the ovigerous cords in the embryonic ovary to follicles later on (Fig. 3).

During sex determination of the ovary, oogonia and granulosa cells assemble to form structures called “ovigerous cords”. Each cord is composed of a germ cell cyst with proliferating oogonia, loosely surrounded by a layer of quiescent granulosa cells. These ovigerous cords are separated from the ovarian stroma by a basement membrane (or basal lamina), a thin layer of extra-cellular matrix. The ovigerous cords remain connected to the surface of the ovary, in contact with the coelomic epithelium, the source of newly differentiating granulosa cells. Depending upon the species, the timing of ovigerous cords formation varies, and their morphology is not always well-defined.

The formation of the ovigerous cords demarcates the two different regions in the embryonic ovary: the cortex and the medulla. The cortex consists of the coelomic epithelium and the region underneath it. Proliferation of the surface epithelium causes the expansion of the cortex. The cells resulting from this proliferation then ingress into the ovary and become a source of granulosa cells. This recruitment of granulosa cells contributes to the development of the ovigerous cords in the fetal ovary and the follicles later in life. The cortex is the region of the ovary where most oocytes accumulate. As the fetal ovary grows, the cortex becomes the predominant region of the organ. The medulla, on the other hand, is the region at the center of the ovary that is closely associated with the adjacent mesonephros. As the ovigerous cords form, the ovarian stroma, composed of non-granulosa somatic cells outside of the cords, migrate from the medulla toward the cortex between ovigerous cords. The ovarian stroma contains precursor cells that give rise to most of the steroidogenic theca cells. Medulla of the ovary is where stroma cells, connective tissue and vasculature concentrate. Ultimately, in the adult ovary, the medulla becomes devoid of follicle, and contains only the vasculature and innervation.

Once ovigerous cords are formed, they gradually become isolated from the ovarian surface epithelium by a basement membrane. During the ovarian morphogenesis, fetal ovaries changes from a long structure full of multiple ovigerous cords to a round structure composed of primordial follicles. This morphological change begins when oocytes enter meiosis, and germ cell cysts within the ovigerous cords begin to break down (Pepling and Spradling, 2001). The germ cell cyst breakdown is the combined result of oocyte death and invasion of granulosa cells between the oocytes. As a consequence, intercellular bridges between the oocytes are disrupted, and germ cell cysts gradually disintegrate and become smaller. The decline in oocyte numbers due to cell death results in an increased ratio of granulosa cells to oocytes within the ovigerous cords. More granulosa cells surround the remaining oocytes and their cytoplasmic extensions enclose each oocyte, isolating the oocyte from the cyst. Eventually, the ovigerous cords disappear to give rise to primordial follicles that are isolated from the stroma by a basement membrane. The process of germ cell cyst breakdown and primordial follicle formation starts in the medulla and expands toward the cortex. The first cohorts of primordial follicles are formed in the medulla while the cortex still contains ovigerous cords that undergo germ cell cyst breakdown. Following the formation of the first cohort of primordial follicle, the majority of the primordial follicles are established in the cortex

region soon after birth. The outcome of the ovary morphogenesis during fetal life ultimately leads to the neonatal ovary that contains primordial follicles, the functional unit of the ovary. These follicles will be responsible for the development of healthy and fertilizable oocytes as well as the production of female hormones in the adulthood.

Female Sex Determination: Molecular

Joan S Jorgensen, Anqi Fu, and Megan Hornung, University of Wisconsin, Madison, WI, United States

Introduction

Sex, or male versus female determination is a critical developmental event in all sexually reproducing organisms. While male versus female sex is typically considered a binary differentiation event, and common sense would dictate a process that is evolutionarily conserved, the diversity and plasticity of sex determination is both fascinating and astounding. The variations across animal kingdoms are vast, but even among vertebrates, diversity in sex determination between species include those that rely on temperature gradients, sex-specific chromosome genes, or other modes of genetic control, many still unknown. Still others, including certain species of fish, mole, or alligators, have the ability to transdifferentiate from one sex to another or harbor remnants of both sexes so that they may expand male or female tissue depending on external cues (Guillette et al., 1997; Jimenez et al., 2013; Wu and Chang, 2013). For mammalian species, it has long been established that sex is determined by XX versus XY chromosome presence with *SRY* (sex determining region of the Y chromosome) identified as the single inciting gene from the Y chromosome that is required to stimulate male development (Hacker et al., 1995). Although this genetic pathway appears straightforward, the diversity in biological presentations suggests otherwise. For example, in humans, there are a wide variety of disorders of sex development (DSDs), many of which remain unexplained. Even if birth defects are not obvious, there is also increasing recognition of people suffering from gender dysphoria, of which there is no known cause. Together, these truths, along with others not mentioned here, suggest that female versus male sex determination might better be represented by a gray scale instead of a black or white outcome.

Unlike any other developing organ, cells within the early gonad have the potential to differentiate into one of two very different organs: a testis or an ovary. While they share the same functional outcome of passing along sex-specific gametes for the next generation, their modes of operation are necessarily quite distinct. In typical XY individuals, the adult testes produce millions of gametes each day that are released in large quantities along with nutritive fluids contributed by accessory sex organs through specially designed ductwork and external genitalia. Meanwhile, in the typical XX individual, the entire population of gametes is present at birth, and in the adult, a single gamete is released once every cycle into its specially designed ductwork that will receive male gametes and provide the protective environment for a new embryo to develop. In both cases, a lifetime of intricately timed sex-specific hormone production is required to successfully achieve each outcome. And in both cases, this coordinated program stems from events that occur in early gonad development.

The Bipotential State

Early on, the paired gonads differentiate and acquire four distinct cell types: (1) support and (2) interstitial/stroma cells that arise from a common mesodermal progenitor, and then (3) endothelial and (4) germ cells that differentiate elsewhere and migrate into the gonad. The initial focus of the nascent developing gonad, like any other newly forming organ, is cell proliferation and survival. Early genes that are known to contribute to this phase include *Lhx9* (Lim homeobox 9), *Wt1* (Wilms tumor 1), *Odd1* (Odd-skipped 1), *Emx2* (empty spiracles homeobox 2), and *Sf1* (steroidogenic factor 1, also known as NR5A1, ADBP4) (Birk et al., 2000; Kreidberg et al., 1993; Luo et al., 1994; Miyamoto et al., 1997; Sadovsky et al., 1995; Wang et al., 2005). Previous studies using knockout models for each of these genes resulted in impaired cell proliferation and gonad agenesis or degeneration. While knockout models of other genes including *Wnt4/Rspo1* (wingless-type MMTV integration site family, member 4, R-spondin homolog 1), *Pbx1* (pre-B-cell homeobox 1) and *Insr/Igfr2* signaling factors (insulin receptor/insulin-like growth factor receptor 1) also disrupted cell proliferation, they were still able to initiate sex determination albeit in rudimentary form (Chassot et al., 2012; Nef et al., 2003; Pitetti et al., 2013; Schnabel et al., 2003) (Table 1).

Ultimately, the support cell population initiates sex determination. Certain somatic cells will differentiate into the support cell precursors, Sertoli cells in XY and granulosa cells in XX, and henceforth, trigger the sex-specific commitment of all other cell lineages (interstitial/stromal, germ, and endothelial cells) within the nascent developing gonad. The onset of *SRY* expression as the initiator of Sertoli cell fate and testis determination was discovered over a decade ago (Gubbay et al., 1990; Koopman et al., 1991; Sekido et al., 2004), but the mechanisms by which granulosa cell fate and ovarian determination is just beginning to be understood. Landmark studies by Alfred Jost suggested that female differentiation was a default pathway because female structures prevailed in XY individuals that lacked male factors (Jost, 1947). In addition, the search for a single XX-female initiating factor has thus far not been fruitful. Instead, studies suggest an active balancing act that imposes mutual antagonism between a cadre of female and male-promoting factors that stabilize the sex-specific fate. Maintenance of either fate depends on an intricate network of molecular controls that include signal cascade pathways along with transcription factor and epigenetic mechanisms for genetic control.

Table 1 Genes associated with cell proliferation in the bipotential gonad

Knockout description	Gene	Gene name	Reference(s)
Impaired proliferation, gonad agenesis or degeneration	<i>Lhx9</i>	Lim homeobox 9	Birk et al. (2000)
	<i>Wt1</i>	Wilms tumor 1	Kreidberg et al. (1993)
	<i>Odd1</i>	Odd-skipped 1	Wang et al. (2005)
	<i>Emx2</i>	Empty spiracles homeobox 2	Miyamoto et al. (1997)
	<i>Sf1 (Nr5a1, AdBP4)</i>	Steroidogenic factor 1 (nuclear receptor subfamily 5 group A member 1, adrenal 4 binding protein)	Luo et al. (1994), Sadovsky et al. (1995)
Impaired proliferation, rudimentary sex determination	<i>Wnt4/Rspo1</i>	Wingless-type MMTV integration site family, member 4; R-spondin homolog 1	Chassot et al. (2012), Nef et al. (2003)
	<i>Pbx1</i>	Pre-B-cell homeobox 1	Schnabel et al. (2003)
	<i>Insr/Igfr2</i>	Insulin receptor/insulin-like growth factor receptor 1	Pitetti et al. (2013)

Sex Determination

Careful analysis of gene expression profiles from embryonic mouse gonads taken at multiple time-points within a 24-h window highlighted two fundamental concepts: (1) both XX and XY gonads harbor all genes necessary for generating either a testis or an ovary, and (2) more female than male genes are expressed at the late bipotential stage, suggesting that a female bias exists (Jameson et al., 2012; Munger et al., 2013). In the early bipotential stage, XX and XY gonad transcriptomes are nearly identical and include typical testis genes *Sox9* (Sry box 9) and *Fgf9* (fibroblast growth factor 9) along with typical ovary genes *Wnt4* and *Rspo1* (Munger et al., 2013; Nef et al., 2005). This stage has been described as a transient balanced transcriptional state with genes associated with either sex poised for activation or repression depending on molecular cues (Lin and Capel, 2015). The presence of a female bias suggests that testis differentiation must provide the means to block the ovary pathway. This is where *Sry* comes in.

Male Sex Determination

It is impossible to discuss female gonad sex determination without some understanding of what's happening in the male. By definition, only XY gonads can express *Sry*, which encodes the transcription factor that tilts the balance of genes toward the testis fate. The timing for SRY activity, however, is critical and exposes a weakness in the male pathway. *Sry*/SRY expression initiates starting at 10.5dpc (days post coitum) in mouse (out of ~19.5 days gestation) (Bullejos and Koopman, 2001; Hacker et al., 1995; Jeske et al., 1995) and between 41 and 44 days post ovulation in humans (out of ~240 days, relatively much sooner) (Hanley et al., 2000). Expression in the mouse is fleeting, only 36 h; whereas SRY expression is maintained in human cells throughout testis development and into adulthood (Hacker et al., 1995; Salas-Cortes et al., 2001). Studies in mouse have shown that *Sry* expression must increase to a certain level within a short timeline (6 h!) to successfully promote the testis fate. Any delay or failure in reaching the defined threshold of expression results in a range of gonad abnormalities from formation of an ovotestis (containing both ovarian and testicular tissue in the same gonad) to formation of an ovary and complete XY sex reversal (Carre and Greenfield, 2014; Hiramatsu et al., 2009). Although the path to increased *Sry* expression is not entirely clear, key regulatory proteins include insulin signaling factors (*Insr/Igfr1*), GADD45G (growth arrest and DNA damage response), MAP3K4 (mitogen-activated protein kinase), and the GATA4/FOG2 (GATA binding protein 4, Friend of GATA 2) transcription complex (Bogani et al., 2009; Gierl et al., 2012; Manuylov et al., 2008; Nef et al., 2003; Tevosian et al., 2002; Warr et al., 2012).

To tilt the balance of gonad genes, SRY stimulates transcription of another member of the same family of transcription factors, *Sox9*, the real powerhouse behind testis determination. The increase in SOX9 presence feeds forward to increase other testis determining genes including its own expression to solidify the Sertoli cell identity and a testis fate. One of these, *Fgf9*, is translated into a factor that is released from Sertoli cells, only to interact with its receptor (FGFR2) on the same or neighboring Sertoli cells (paracrine signaling) to amplify *Sox9* expression (Bagheri-Fam et al., 2008; Colvin et al., 2001; Kim et al., 2007; Kim et al., 2006; Siggers et al., 2014). *Fgf9* and *Fgfr2* will come up again later in the discussion regarding mutual antagonism of male versus female genes. Finally, SOX9 stimulates transcription of *Ptgds* (prostaglandin D2 synthase), which encodes another signaling molecule, PGD2 that provides paracrine signaling to promote a positive feedback loop on *Sox9* transcription (Adams and McLaren, 2002; Moniot et al., 2009; Wilhelm et al., 2005). Unlike *Sry* in the mouse, *Sox9* expression is maintained throughout life where it plays a central role in reinforcing the Sertoli cell identity.

Female Sex Determination

RSP01/WNT4/ β -catenin

The strength of the female bias in genetic expression eventually tips toward ovary development if SRY is not present to block it. The first female genes that increase are *Wnt4* and *Rspo1* (Jameson et al., 2012; Munger et al., 2013). Both of these genes encode signaling factors that stimulate activity within support cells to facilitate accumulation of β -catenin in the cytoplasm. β -catenin can then be transported to one of two different locations in the cell: the cell membrane or the nucleus (Gottardi and Gumbiner,

2004). At the cell membrane, β -catenin interacts with other adhesion proteins to promote cell–cell adhesion and communication. Alternatively, in the nucleus, β -catenin interacts with particular protein partners, for example TCF/LEF (T-cell factor/lymphoid enhancer-binding factor), that bind to DNA sequences to stimulate transcription of specific WNT4/RSPO1-responsive genes. The identity of these downstream genes is still unclear, but some notable factors include *Fst* (Follistatin), and *Irx3/Irx5* (Iroquois homeobox family members 3 and 5), each of which contributes to WNT4/RSPO1 activity (Jorgensen, 2013; Yao et al., 2004) (Fig. 1).

Each aspect of the WNT4/RSPO1/ β -catenin pathway has been knocked out in mice; notably, their loss does not cause female to male gonad sex reversal, but they are all similarly masculinized (Liu et al., 2009; Tomizuka et al., 2008; Vainio et al., 1999). Common features include abnormal formation of the large coelomic vessel, differentiation of functional steroid producing cells, and massive oocyte death before birth. Activation of β -catenin and *Wnt4* requires RSPO1 signaling within early ovaries, but once activated, WNT4 can synergize with RSPO1 to further increase β -catenin activity (Chassot et al., 2008). In general, mutations of WNT4 in humans can cause a variety of phenotypes that may range from a masculinized outcome that is remarkably similar to the mouse models, to those that are much more severe, including female to male sex reversal. Altogether, the complexities behind the range of outcomes in individuals with WNT4 mutations support the idea that the relative amount or dosage of WNT4 activity is key to female versus male differentiation (Biason-Lauber, 2012). Meanwhile, human mutations of RSPO1 also exhibited more severe abnormalities in sex differentiation than in the mouse. Indeed, at least two reports identified RSPO1 mutations that caused complete female to male sex reversal in patients (Parma et al., 2006; Tomaselli et al., 2008). There is currently no explanation for the difference seen in outcomes for humans versus mice. It is noteworthy, however, that these reports marked the first occasions that complete female to male sex reversal had been attributed to something other than translocation of SRY, which still only explains approximately 10% of these cases, the remainder are still unsolved.

FOXL2

While *Wnt4* and *Rspo1* are present in the bipotential gonad of both sexes, *Foxl2* is never detected in the XY gonad. Similar to *Wnt4*/*Rspo1*/ β -catenin mutant mice, knockout of *Foxl2* does not cause female to male sex reversal and ovarian defects are not apparent until after birth (Schmidt et al., 2004; Uda et al., 2004). Likewise, human patients with FOXL2 mutations exhibit ovarian defects associated with premature ovarian insufficiency in adult female and no sex reversal (Crisponi et al., 2001). In the goat, however, loss of FOXL2 causes female to male sex reversal and is considered a female determining gene (Boulanger et al., 2014). The diversity of outcomes among species caused by a lack of FOXL2 function is intriguing and in this case, has been explained by the timing of its expression in relationship to the onset of meiotic division, and the ovary's ability to make and respond to estrogen (Pannetier et al., 2016).

In the mouse, *Foxl2* expression initiates after the gonad has already tilted toward the ovarian path at approximately 12.5dpc (Schmidt et al., 2004). The onset of FOXL2 expression coincides with support cell transition to mitotic arrest and marks

Fig. 1 Canonical Wnt/Rspo1 signaling leads to β -catenin induced transcription. Left: Without a Wnt or Rspo1 ligand present at the membrane receptors Frizzled (Fzd) or Lrp5/6, a destruction complex forms, targeting β -catenin for degradation by the proteasome. Right: If Wnt or Rspo1 ligands bind to the membrane receptors, the destruction complex cannot form, allowing β -catenin to stabilize and translocate to the nucleus to bind to its DNA binding partners TCF/LEF family members. This will turn on ovary target genes such as *Fst*, *Irx3*, or *Irx5*.

differentiation to the pre-granulosa cell fate (Maatouk et al., 2013). This is also just about the time that germ cells begin to transition from mitotic to meiotic division. Although loss of *Foxl2* doesn't appear to affect the fetal ovary, within a week after birth, ovarian cells that were meant to carry on a granulosa cell fate transdifferentiated into SOX9-positive, male support cells (Ottolenghi et al., 2005; Schmidt et al., 2004; Uhlenhaut et al., 2009). In the mouse, the ovary does not synthesize estrogen until after birth. Thus, the delay in support cell transdifferentiation has been attributed to the timing of estrogen synthesis, which will then allow FOXL2 to interact with the estrogen receptor (ESR1) to suppress *Sox9* and maintain the female support cell program (Uhlenhaut et al., 2009). Further, FOXL2 can then interact with ESR1 and ESR2 (estrogen receptor beta) along with other nuclear receptor transcription factors to impact estrogen production itself (Georges et al., 2014). Meanwhile, in the goat, FOXL2 enhances the ovary's ability to make estrogen at a time that corresponds to sex determination, far earlier than in the mouse (Boulanger et al., 2014) (Fig. 2). These interactions have yet to be described in human perinatal ovaries, but they are known to impact sex determination in several other non-mammalian vertebrate species including reptiles, birds, and fish, making an intriguing case for *Foxl2*, *Esr1*, and *Esr2* as female-determining genes (Nakamura, 2010).

RSP01/WNT4/ and FOXL2 in pre-granulosa cell proliferation and differentiation

Proliferation of support cells is a fundamental difference between female and male gonad differentiation just after the onset of SRY expression (Schmahl and Capel, 2003; Schmahl et al., 2000). Careful studies in mice showed that just after *Sry* turns on and then stimulates *Fgf9*, there is a discrete 8-h window of time in which the testis increases in size. In fact, if FGF9 activity or cell proliferation is blocked during this time frame, male-specific genes and cell types fail to differentiate and the testis fate is thwarted (Schmahl and Capel, 2003; Schmahl et al., 2004). In contrast, support cells of the female gonad transition to mitotic arrest once they differentiate into pre-granulosa cells. There are, however, two different transition events and the timing of each marks the future follicles into one of two populations. All support cells appear to originate from a common precursor lineage that is positive for transcription factors GATA4, IRX3, and IRX5 (Manuylov et al., 2008) (Fu et al., 2018). The first population of precursor cells enters mitotic arrest and express cell cycle inhibitor factors including p27, p21, and p57 along with FOXL2 (Bouma et al., 2007; Jameson et al., 2012; Mork et al., 2012). These cells remain in mitotic arrest until after birth, when they are activated and recruited as granulosa cells that are destined for the first wave of follicles that mature within the medulla of the ovary. They facilitate the onset of puberty and early fertility (Mork et al., 2012; Rastetter et al., 2014; Zheng et al., 2014). The surface epithelium of the developing ovary, however, express WNT4/RSP01 and RSP01 receptor, LGR5, and remain proliferative until they exit the surface and then transition to mitotic arrest as they begin to contribute to the support cell pool (Gustin et al., 2016; Hummitzsch et al., 2013). Once they leave the ovarian surface, they begin to express FOXL2 and differentiate into granulosa cells that remain quiescent within primordial follicles in the ovary cortex until recruited later after puberty (Mork et al., 2012; Zheng et al., 2014). What helps to maintain this quiescent state? Studies indicate that oocyte status in regard to their transition into meiosis plays an important role in communicating granulosa cell activity during fetal development (Maatouk et al., 2013). These studies highlighted the first meaningful outcome in ovary differentiation that results from interactions between support cells and oocytes.

Fig. 2 Comparison of FOXL2–estrogen/ESR1/ESR2 interactions in the ovary across different mammalian species: The onset of FOXL2 and estrogen signaling via estrogen receptors, ESR1 and ESR2 differ between human, mouse, and goat. In the goat, FOXL2 can interact with estrogen-bound ESR1 and ESR2 to block *Sox9* at the time of sex determination and before the onset of meiosis. In the mouse, FOXL2 is present just after sex determination and before the onset of meiosis; however, estrogen is not active until after birth. In the human, FOXL2 and estrogen are present before the onset of meiosis; however, the timing for estrogen receptor-mediated activity is unknown. wpf, week post fertilization; dpc, days post coitum; timeline not drawn to scale.

Mutual Antagonism

The initial status of the developing gonad is bipotential as it harbors genetic signatures that are typically associated with both male and female pathways. Once the molecular cues within gonad support cells tilt toward one particular sex, those cells maintain their sex-specific fate and steer other resident cells, including germ cells, toward the same sex-specific outcome. Historically, this decision was considered irreversible. Recent studies, however, suggest otherwise. Instead, key factors have been shown to play dual roles during gonad development: they promote sex determination while they actively antagonize the molecular pathways of the opposite sex. This should not be a big surprise as it has long been established that other vertebrate species can readily transdifferentiate from one sex to another in response to external cues. Ultimately though, the mammalian species are less susceptible to external cues and transdifferentiation from one committed fate to another is unusual and no human case has been reported.

Antagonistic relationships exist among the major sex determining factors and are maintained from developmental stages through adulthood (for review, see [Wilhelm et al., 2013](#)). First, consider the developmental state and sex-determining factors present in the bipotential gonad, SOX9/FGF9 and the RSPO1/WNT4/ β -catenin pathways. In male gonads, knockout of *Sox9*, *Fgf9* or its receptor, *Fgfr2*, causes partial to complete male to female sex reversal ([Bagheri-Fam et al., 2008](#); [Chaboissier et al., 2004](#); [Colvin et al., 2001](#); [Kim et al., 2006](#); [Siggers et al., 2014](#)). Notably, in *Fgf9* or *Fgfr2* null testes, expression of *Wnt4* increased dramatically suggesting the FGF9 pathway plays an active role in suppressing the female pathway ([Kim et al., 2006](#)). These findings were supported by double knockout studies in which elimination of any member of the *Rspo1/Wnt4/Ctnnb1* (β -catenin) pathway along with *Fgf9* or *Fgfr2* allowed for rescue of the male to female sex reversal ([Jameson et al., 2012](#)). Given the relationship that SOX9 and FGF9 mutually support each other, it was not surprising to find that, double knockout of *Sox9* along with any member of the *Rspo1/Wnt4/Ctnnb1* pathway also blocked the male to female sex reversal ([Lavery et al., 2012](#); [Nicol and Yao, 2015](#)). The power of the β -catenin pathway to block male differentiation is especially illustrated in XY gonads that exhibit male to female sex reversal when male support cells over-express the stabilized form of β -catenin ([Maatouk et al., 2008](#)). In the case of the female gonad, loss of any member of the *Rspo1/Wnt4/Ctnnb1* pathway caused increased expression of *Sox9* and *Fgf9* and incomplete female–male sex reversal; however, this phenotype was not rescued after either of these factors was also eliminated ([Kim et al., 2006](#); [Nicol and Yao, 2015](#)). These studies suggest that the β -catenin pathway blocks male-driving factors in addition to *Sox9* and *Fgf9*, such as other Sox family members ([Nicol and Yao, 2015](#)).

Other antagonistic relationships that maintain sex fate are not manifested until after birth. Identity of Sertoli and granulosa cells in adult testis and ovary, respectively, is mediated by transcription factor activity. In the adult testis, the highly conserved male promoting factor, DMRT1 (doublesex and mab-3 related transcription factor 1) promotes testis-specific factors while repressing ovary-driving genes ([Minkina et al., 2014](#)). Indeed, elimination of *Dmrt1* in the adult testis causes significant reductions in *Sox9* and activation of *Foxl2* to result in Sertoli–granulosa cell transdifferentiation ([Matson et al., 2011](#)). On the flip side, the presence of DMRT1 alone was sufficient to silence *Foxl2* and reprogram granulosa cells into Sertoli cells in the adult ovary ([Lindeman et al., 2015](#)). Also in the adult mouse ovary, the aforementioned transcription factors FOXL2 and activated estrogen receptors (ESR1 and ESR2) have been shown to interact with critical enhancer sequences to repress *Sox9* transcription ([Matson et al., 2011](#); [Minkina et al., 2014](#); [Uhlenhaut et al., 2009](#)). Knockout of *Foxl2* in adult granulosa cells was sufficient to cause rapid upregulation of *Sox9* and *Dmrt1* transcription followed by granulosa and theca cell transdifferentiation into Sertoli and Leydig cells ([Uhlenhaut et al., 2009](#)) ([Fig. 3](#)). As might be expected, these transdifferentiation events destined all germ cell populations to death.

Epigenetics

The developmental program of any organ depends on exquisite timing of gene expression as cell fates are decided. Appropriate timing is defined by the activity of relevant transcription factors along with the nature of the chromatin environment or epigenetic marks of the collection of sex determination genes. Epigenetics is defined as the molecular approach for genetic activity that does not depend on the DNA sequence itself. Instead, epigenetic control is typically mediated by reading biochemical marks that decorate DNA. These marks are inherited and reversible, so biochemical reactions along the DNA can switch genes on or off depending on other cellular signals. The major marks include methyl (–CH₃) and acetyl groups that affix themselves to the DNA itself or to histone proteins that surround the DNA sequences. Their addition will cause chromatin to either coil up tightly (high levels of DNA methylation, some forms of histone methylation) to silence genes, or relax (low levels of DNA methylation, some forms of histone methylation and acetylation) to allow access and stimulate gene transcription. Recent studies used DNase1-Seq technology to uncover thousands of open chromatin sites that were unique to Sertoli cells just after sex determination, a subpopulation of these were also positive for histone acetylation binding. Together, these new data illustrate the possibility that there are collections of sites that are available for either repressor or activator regulation ([Maatouk et al., 2017](#)).

The first solid piece of evidence for epigenetic control for sex determination was the discovery that *Sry* gene activity was controlled by DNA methylation status ([Nishino et al., 2004](#)). Since then, studies have also shown that *Sry* transcription is also under the control of chromatin binding protein CBX2 and histone demethylase enzyme activity ([Biaison-Laubier et al., 2009](#); [Katoh-Fukui et al., 2012](#); [Kuroki et al., 2013](#)). The most exciting discoveries cementing the role for DNA methylation activity and sex determination have been in non-mammalian vertebrate species. The link between temperature and sex determination has long been a mystery. Recently, several groups have shown that temperature gradients exert tight control of DNA methylation of critical

Fig. 3 *Mutual antagonism during gonad development.* Summary of mutual antagonism between male promoting factors (blue) and female promoting factors (pink) during gonad development through adulthood. sex determination genes including *Sox9* and *Cyp19a1*, the enzyme responsible for the final step in estrogen synthesis (Navarro-Martin et al., 2011; Parrott et al., 2014). At this time, however, epigenetic control remains a mystery. For example, in the absence of SRY-SOX9 action, what controls upregulation of the *Rspo1/Wnt4/Ctmb1* pathway? How are dosages for critical genes such as *Sry* ramped up or down? What senses the intricate timing schedule? Clearly, there is much to discover and new discoveries are awaited with anticipation.

Conclusions

Sex determination is a fascinating process that illuminates the beautiful diversity of living beings. When the process is disrupted, variations of disorders of sex differentiation can occur. While not life threatening, at least in humans, successful management requires an entire team of medical and social support networks for both patient and family. As increasingly sophisticated tools become available, researchers have set increasingly realistic goals to identify causes that will lead to ways to prevent and reverse potential disorders.

Development of the Primordial Follicle

What is a Primordial Follicle?

A human primordial follicle is approximately 40 μm in diameter, and comprised of a 30 μm oocyte in the center of approximately 10 squamous pregranulosa cells (Fig. 1; Townson and Combelles, 2012). Although not exclusive to any part of the ovary, primordial follicles are typically located in the peripheral cortex of the ovary rather than the inner medulla (Sforza et al., 2003). Primordial follicles contain a Balbiani body which is a unique assembly of cytoplasmic organelles including mitochondria and Golgi bodies associated with the nucleus of germ cells. In mice, the Balbiani body develops during germ cell cyst breakdown and primordial follicle assembly and is no longer present in the oocyte after primary follicle formation (Pepling et al., 2007). The total number of primordial follicles within the ovary at the time of birth is considered a finite pool from which the reproductive system will draw from over a lifetime. Although some research posits that there are cells within the adult human ovary that may be capable of forming new germ cells, through a process called neooogenesis (Virant-Klun, 2015), such studies remain to be confirmed independently and contrast with the evidence provided by a wealth of controlled mouse genetic studies (Zarate-Garcia et al., 2016). In humans, primordial follicles that make up the adult ovarian reserve are arrested in meiotic prophase I and remain quiescent until being activated for ovulation, which can be decades later (Pelosi et al., 2015). However, most reawakened follicles end up undergoing atresia, a specialized form of apoptosis of oocytes and their mature granulosa cells. For clinical purposes, there is not a test available that will directly assess the number of quiescent primordial follicles in the ovarian reserve (Gleicher et al., 2011). However, there is a strong and positive correlation between ovarian volume and the number of primordial follicles within the human ovary, with approximately 1000 primordial follicles corresponding to 3.01 cm^3 of ovarian volume (Kelsey and Wallace, 2012). Indirectly, the human ovarian reserve can be measured via serum AMH levels secreted by granulosa cells of the primordial follicle pool (van Rooij, 2002). In the following sections, we will discuss the developmental steps and dynamics that take place to establish the proper primordial follicle pool.

Germ Cell Numbers Over Time

In 1963, T.G. Baker published a seminal paper that estimated the population dynamics of the human ovarian reserve over time. This study posited that approximately one million oocytes were present in newborn females, which is often repeated amongst lay and scientific communities alike (Baker, 1963). A more precise estimation of how many oocytes within primordial follicles are present at the time of birth is less certain and seemingly more variable between individuals than the estimate Baker proposed. A more recent and comprehensive estimation of the primordial follicles within the human ovarian reserve suggests the peak number of follicles to be present at 18–22 weeks post fertilization (wpf) of approximately 300,000 non-growing follicles per ovary, with a 95% prediction interval of 35,000–2,534,000 follicles. Furthermore, the population at the time of birth is estimated to be similar at 295,000 follicles with a 95% prediction interval of 34,000–2,508,000 cells (Wallace and Kelsey, 2010). While in similar ranges as Baker first proposed, these large prediction intervals illustrate the general uncertainty surrounding the size and dynamics of the human ovarian reserve. In female mice, where genetic background, tissue procurement and environment can be controlled, these numbers are much clearer and help inform us how the mammalian ovary regulates oocyte numbers through development. At embryonic day 7.25 (E7.25), bone morphogenetic protein (BMP) signaling instructs approximately 40 primordial germ cells (PGCs) to form in the embryonic mesoderm. These initial PGCs migrate to the genital ridge from E8.5 to E10.5 and during this journey undergo mitosis with incomplete cytokinesis until E14.5. Incomplete cytokinesis of these PGCs creates “germ cell cysts” or “germline cysts” (discussed further in the next section). The peak number of PGCs at E14.5 is approximately 20,000 germ cells per ovary and this number decreases over time as many germ cells undergo apoptosis

Fig. 1 Anatomy of a primordial follicle. Schematic diagram of a mammalian primordial follicle which is composed of a layer of squamous pregranulosa cells surrounding a single oocyte. The oocyte contains meiotic chromosomes arrested in the diplotene stage of prophase I, and a specialized perinuclear Golgi and mitochondrial cloud called a Balbiani body (green circle). The oocyte cytoplasm (dark yellow) and nucleus (light yellow) are highlighted.

during cyst breakdown. By postnatal day 4 (PND4) approximately 4000 meiotically arrested oocytes per ovary survive thus establishing the initial primordial follicle pool and subsequent ovarian reserve (Ikami et al., 2017).

Germ Cell Cyst Formation and Breakdown

The formation of germ cell cysts in the human fetal ovary occurs 5–16 wpf (Wang et al., 2017) and is evolutionarily conserved across vertebrate species, including fish, frogs, and mammals (Pepling and Spradling, 1998; Filosa and Taddei, 1976). Much of our current understanding of this process in mammals is based upon extensive studies of oogenesis in the invertebrate model organism *Drosophila melanogaster*. The germline cyst in *Drosophila* is comprised of 16 cells in which their cytoplasm is connected through ring canals (Jenkins et al., 2013). Of these 16 cells within the cyst, there are two cells that have four ring canal connections. One of these two cells is designated to become the oocyte and the rest become nurse cells for the oocyte (Hong et al., 2003). These intercellular bridges allow for the movement of RNA, proteins, and organelles from the nurse cells into the developing oocyte within the cyst (Marlow, 2010).

In mammals, there are similar strategies implemented for determining and nourishing developing oocytes. Mouse female germ cells also form germline cysts through mitotic divisions with incomplete cytokinesis and are connected through cytoplasmic bridges (Pepling and Spradling, 1998) and these cysts begin to breakdown at the time of birth (Pepling and Spradling, 2001). At their greatest number, there are approximately 30 germ cells in a cyst. However, the functionality of these cytoplasmic bridges as ring canals in mammals has been disputed. Intercellular bridges using ring canals require the protein TEX14 to connect male germ cells but female *Tex14*-knockout mice are fertile. This suggests that in mammals, the ring canal connections between germ cells in a cyst are an evolutionary vestige rather than an essential development structure (Greenbaum et al., 2009). Alternatively, TEX14 function might be redundant with other proteins expressed in the cytoplasmic bridges in the developing mammalian ovary. Most importantly, the surviving oocytes still gain many useful organelles from other germ cells in the cyst that are destined to undergo apoptosis. It has been demonstrated that centrioles, Golgi, and mitochondria are moved into the surviving oocyte through cell membrane connections rather than ring canals. This would explain why TEX14 is not necessary for female fertility. This transfer of cellular equipment into the surviving oocyte leads to the Balbiani body forming within the oocyte (Lei and Spradling, 2016). After germ cell cyst breakdown and survival of specific oocytes, only 20% of the original germ cells in the cyst remain (Lei and Spradling, 2016). Thus, comparing how invertebrates and vertebrates initiate oogenesis has been an invaluable asset to our understanding of human oogenesis.

Primordial Follicle Assembly

Primordial follicle assembly is characterized by a minority of individual oocytes within the developing ovary being enveloped by a layer of squamous pregranulosa cells (Fig. 2). The majority of early oocytes that do not assemble into primordial follicles are lost by apoptosis. Formation of the primordial follicle occurs in mice after birth and in humans as early as 14 wpf, but is more common at 18 wpf (Pepling, 2006; Coward and Wells, 2013). The productive interaction of pregranulosa cells and their corresponding oocyte is critical for establishing the proper ovarian reserve during embryogenesis (Nicol and Yao, 2014). While the bidirectional communication between granulosa cells and oocytes during folliculogenesis in the adult is well characterized, how these cells first initiate their intimate and critical relationship remains to be further illuminated.

Pioneering genetic studies of the forkhead transcription factor FOXL2 indicated that proper differentiation of embryonic pregranulosa cells was required for development of the primordial follicle pool in the postnatal mouse (Schmidt, 2004). Strikingly, mutation of the human *FOXL2* gene causes blepharophimosis/ptosis/epicanthus inversus syndrome (BPES) type I, which is a rare eye malformation and associated with primary ovarian insufficiency (Crisponi et al., 2001; De Baere et al., 2001). Together these studies suggest that proper differentiation of pregranulosa cells is highly regulated during embryonic development and critical for proper human fertility.

Fig. 2 Temporal regulation of mouse primordial follicle assembly. Based on extensive mouse genetic and developmental studies, formation of primordial follicles covers embryonic (E) and postnatal day (PND) timepoints. At E13.5, mitotically active oogonia begin meiotic differentiation. By PND4, oocytes are arrested in prophase I of meiosis and cyst breakdown is complete forming a finite pool of individual primordial follicles. Genes regulating entry into meiosis and the early development of primordial follicle are indicated in *black font*. Environmental toxicants known to disrupt these early steps in primordial follicle development are indicated in *red font*.

One of the major challenges to understanding the function of specific genes in pregranulosa cell-dependent regulation of primordial follicle assembly is that potential regulators are often expressed both in oocytes and somatic pregranulosa cells. The transcriptional regulator of primordial follicle development TAF4b is expressed in both oocytes and pregranulosa cells and may direct unique transcriptional programs in each cell type (Grive and Freiman, 2015). In such cases, assigning precise cell type-specific function to individual genes and signaling pathways is difficult. However, recent studies in mice have begun to identify pregranulosa-specific factors, functions and mechanisms that drive establishment of the initial primordial follicle pool. For example, deletion of the transcription factors *Gata4* and *Gata6* in embryonic pregranulosa cells prevents formation of the initial primordial follicle pool (Padua et al., 2014). These studies further support the notion that highly regulated pregranulosa cell-specific functions are essential for proliferation and/or differentiation of pregranulosa cells to support oocyte nest breakdown and embryonic formation of the adult ovarian reserve. Adding to this complexity, recent evidence supports the existence of heterogeneity amongst pregranulosa cell and primordial follicle populations that arise in the embryonic ovary (Harikae et al., 2013; Zheng et al., 2014). Thus, future studies are required to identify the molecular nature of these sub-populations of pregranulosa cells and primordial follicles and how they may uniquely contribute to mammalian fertility.

Further progress has been made in understanding oocyte-specific genes that contribute to primordial follicle assembly. Two genes that have come into focus as important for primordial follicle assembly expressed in the oocyte are *Figla* and *Nobox*, both transcription factors that regulate the expression of other genes. *Figla*-null mice suffer from infertility due to a lack of primordial follicles and its encoded protein Figla has been shown to regulate multiple germ cell-specific genes in the embryonic ovary while repressing male germline genes (Soyal et al., 2000; Joshi et al., 2007). The human *Figla* homolog is expressed in primordial follicles and is correlated with the development of these follicles (Huntriss et al., 2002; Bayne et al., 2004). Similar to Figla, Nobox expression is thought to repress male germline gene expression and is needed for proper cyst breakdown, oocyte survival, and primordial follicle assembly in mice (Choi et al., 2007; Rajkovic et al., 2004). When Nobox is absent, there is impaired invasion of pregranulosa cells into the germ cell cysts for primordial follicle formation (Lechowska et al., 2011). The common theme that transcription factors play a critical role in primordial follicle development suggests that particular sets of gene networks are exquisitely regulated in a stage and cell type-specific manner to initiate this process for successfully for subsequent fertilization and development.

Primordial Follicle Quiescence and Maintenance

In humans, quiescent follicles must have the potential to survive a woman's reproductive lifespan of about 50 years (McGee and Hsueh, 2000). The dormant primordial follicles are mainly localized to the outer cortical areas of the adult human ovary (Leung et al., 2004). While this quiescence phase is the longest state of a female gamete's life, how exactly this phase is maintained is not well understood. It has been shown that inhibitory factors repress the activation of the primordial follicle from entering folliculogenesis and survival factors prevent primordial follicle loss via apoptosis (Reddy et al., 2010). The major genes and pathways that support these concepts have been identified using mutant mouse genetic models. For example, the PTEN signaling pathway, which includes genes like *Foxo3a*, is believed to be critical for germ cell quiescence due to premature primordial follicle activation in mice (Fig. 2; Castrillon et al., 2003; Reddy et al., 2008). Furthermore, factors that promote primordial follicle survival are also connected to this pathway such as 3-phosphoinositide-dependent protein kinase-1 (PDK1), whose loss in germ cells causes early primordial follicle death (Reddy et al., 2009). The further understanding of what genes and pathways contribute to primordial follicle quiescence and survival will need to be improved by future research in rodents and other large animal models in addition to further examination of these signaling pathways in the context of the human ovary.

Meiosis Initiates Within the Developing Oocyte

Meiosis During Oogenesis

Concurrent with germ cell cyst breakdown and primordial follicle development, prophase I of meiosis I has begun. Meiosis is the process by which a single germ cell duplicates its genome and divides twice into haploid daughter cells. The gametes that are produced by this process provide half the genetic information to the next generation. In female mammals, meiosis begins during embryonic development and is critical for establishing a functional ovarian reserve. In this section, we will briefly cover the stages of meiosis that occur and are critical for proper primordial follicle development.

Meiotic Initiation

The reductive divisions of meiosis begin with DNA replication. In mice, meiotic initiation begins at embryonic day 13.5 (E13.5, Fig. 2) and in humans at 11 wpf (Childs et al., 2011; Coward and Wells, 2013). In the developing mouse ovary, meiosis initiates and progresses through a synchronous anterior to posterior wave, whereas human meiosis progresses less synchronously but generally more developed oocytes are in the medulla of the ovary in comparison to the peripheral cortex (Menke et al., 2003; Le Bouffant et al., 2010; Childs et al., 2011). Retinoic acid (RA) and stimulated by retinoic acid 8 (Stra8) are critical for meiotic initiation. In mice RA signaling originates from the adjacent mesonephros, an organ that acts as a transient embryonic kidney, and induces Stra8 expression in the oocytes via retinoic acid receptors (Feng et al., 2014; Gray and Cohen, 2016). Stra8 expression is the first indication that meiosis has begun in the oocyte and is critical for both pre-meiotic DNA replication and proper execution of prophase I (Baltus

et al., 2006). Despite being discovered in 1995 and studied extensively, the function of the STRA8 protein remains unknown (Bouillet et al., 1995; Oulad-Abdelghani et al., 1996; Feng et al., 2014). In humans, it is believed that similar mechanisms occur to promote meiotic initiation, however RA signaling, and thus the cue for meiotic initiation, instead originates from the ovary, rather than the mesonephros (Le Bouffant et al., 2010; Childs et al., 2011). Many aspects of meiotic initiation are not well understood, especially in regards to the regulation of gene expression associated with promoting the timely initiation of meiosis that directly leads to the establishment of the proper adult ovarian reserve.

Primordial Follicle Stages of Meiosis—Prophase I

Female mammalian oocytes progress through prophase of meiosis I (prophase I) before arresting for the duration of primordial follicle quiescence. During this process, chromosomes condense, synapse, recombine, repair and then arrest until primordial follicle activation. These actions within prophase I are often broken down into five distinct steps of development:

Leptotene

Leptotene, also known as leptonema, is based in the Greek meaning “thin thread” due to the thin strands the oocyte’s chromosomes are at this stage (Gilbert, 2016). Leptotene is predominantly observed in oocytes at E14.5 in mice and approximately 13 wpf in humans (Borum, 1961; Coward and Wells, 2013). Chromosomes are loosely condensed and connections between sister chromatids are formed during leptotene through axial elements (AEs), which connect the sister chromatids from end to end. At this point, the homologous chromosomes, which each have a sister chromatid due to pre-meiotic DNA replication, are not rigidly attached to one another. Double-stranded DNA breaks also occur in preparation for genetic recombination and repair by non-sister homologous chromosomes. While the process of DNA recombination requires many steps and proteins, PRDM9 is a methyltransferase that works in both mice and humans as a marker of meiotic recombination hotspots and SPO11 is a topoisomerase that is responsible for breaking the DNA strands (McNicoll et al., 2013; Gray and Cohen, 2016).

Zygotene

Zygotene, also known as zygonema, comes from the Greek meaning “yoked threads” due to the chromosomes becoming slightly more condensed and homologous chromosomes beginning to attach using the synaptonemal complex (SC), a set of proteins appropriately named synaptonemal complex protein 1–3 (SYCP 1–3) that zip up the homologous chromosomes from end to end. The zygotene substage of prophase I predominantly occurs at E14.5 but also can be found at E15.5 and E16.5 in mouse development (Borum, 1961). Similarly, zygotene in human development can first be observed at approximately 14 wpf (Coward and Wells, 2013). DNA repair proteins such as MSH4/MSH5 localize to sites of DNA damage induced for meiotic recombination by SPO11. Most DNA double-stranded breaks will not result in genetic crossover between homologous chromosomes, but instead be simply repaired (Bolcun-Filas and Schimenti, 2012; Gray and Cohen, 2016).

Pachytene

Pachytene, also known as pachynema, comes from the Greek meaning of “thick thread” because by this stage the homologous chromosomes are synapsed, or have been fully zipped up and are connected from end to end by the synaptonemal complex. This fully synapsed unit of chromosomes is referred to as a tetrad. Pachytene can begin to be observed as early as E15.5 in mice but can be found in oocytes up until the time of birth and in humans can begin to be observed at approximately 16 wpf (Borum, 1961; Coward and Wells, 2013). During this time, strand invasion and meiotic recombination occurs and is repaired by the end of pachytene. The DNA repair mechanisms tend to favor the homologous chromosome as the template for DNA repair over using the sister chromatid. However, the basis for the concept of homolog preference comes from studies in yeast and the facilitating proteins do not have clear homologues in mice and humans but the proteins HORMAD1 and HORMAD2 are suspected to be such homologues (McNicoll et al., 2013; Bolcun-Filas and Schimenti, 2012; Rinaldi et al., 2017).

Diplotene

Diplotene, or diplonema, meaning “double threads” is the final substage of prophase I and retains the compact appearance of pachytene chromosomes that appear more Y-shaped due to the loss of the synaptonemal complex between the homologous chromosomes except in a few areas where meiotic recombination occurred. These points of contact that tether the chromosomes together are called chiasmata. In mice, diplotene is observable during late gestation time points such as E17.5, with nearly all oocytes reaching this stage by postnatal day 2 (PND2), and in humans can begin to be observed at approximately 18 wpf (Dutta et al., 2016; Borum, 1961; Coward and Wells, 2013).

Meiotic arrest

Oocytes remain arrested in diplotene until meiotic resumption weeks to months later in mice and decades later in humans. Cell cycle regulators such as nitrous oxide (NO) and cyclic guanine monophosphate (cGMP) promote meiotic arrest. Meiotic oocytes that are removed from their somatic surroundings are capable of spontaneous resumption of meiosis, indicating that factors from the somatic cells are important for inhibiting this resumption (Tiware et al., 2017). One major remaining question is how does the ovary maintain these dormant cells over such long periods of time and how time affects the quality of these oocytes. Human trisomies are more frequent when compared to other species and these defects can originate early in meiosis. Furthermore,

the incidence of genetic defects increases with maternal age, although the molecular mechanisms for why these defects arise are largely unclear. One major model for age-related aneuploidy is that cohesin proteins that bind sister chromatids together within a tetrad degenerate with age due to many possible factors including premature loss of protection or oxidative damage (Cheng and Liu, 2017). Other factors underlying meiosis I aneuploidies remain to be understood but likely are critical in the development of human birth defects like fragile X syndrome one of the most common causes of childhood intellectual disability.

Disruption of the Primordial Follicle Reserve and Infertility

Environmental Susceptibility of Primordial Follicle Development

The ovarian reserve, and thus a woman's reproductive potential, is dependent upon the population of properly developed primordial follicles during fetal ovarian development. After primordial follicle assembly, follicles enter a long phase of dormancy. Both primordial follicle assembly and the ability to remain quiescent are vulnerable to errors in development and environmental insult. For example, multi-oocyte follicles (MOFs) have been observed in many species including mice and humans (Iguchi and Takasugi, 1986; Telfer and Gosden, 1987). There is no single cause underlying the formation of MOFs, but both environmental contaminants such as exposure to estrogenic substances and genetic defects have been demonstrated to increase the frequency of multi-oocyte follicles (Yan et al., 2001; Iguchi and Takasugi, 1986).

The potential mechanisms leading to the early demise of primordial follicle assembly and MOF development has been intensively studied in rodents where precise doses of environmental toxicants can be assessed in the context of isogenic strains. A major result of this research has led to the importance of the estrogen signaling pathway in the formation of the normal primordial follicle pool (Chen et al., 2007) and how sensitive this developmental process is to estrogen disrupting chemicals (EDCs). The well-studied and ubiquitous EDC bisphenol A (BPA) has been shown to disrupt multiple aspects of early primordial follicle development in both mice and non-human primates (Zhang et al., 2012; Hunt et al., 2012). In addition, embryonic exposure to the phytoestrogen genistein has been shown to disrupt primordial follicle assembly leading to MOFs (Jefferson et al., 2006; Cimafranca et al., 2010; Patel et al., 2017). Strikingly, prenatal exposure to a mixture of phthalates, a ubiquitous plasticizer, can lead to multi- and transgenerational effects on female reproduction (Zhou et al., 2017). A recent study implicates embryonic exposure of the herbicide atrazine in the early demise of the primordial follicle pool (Gely-Pernot et al., 2017). Taken together with the genetic factors affecting this process, establishing the primordial follicle pool is a critical window in development that is highly regulated and sensitive to diverse perturbations.

Early Aspects of Later Infertility

The average woman's ovarian reserve lasts for approximately 55 years before being depleted during menopause. While the timing of reproductive senescence is highly variable between individuals, many cases of reduced female fertility are caused by primary ovarian insufficiency (POI). Affecting 1% of women worldwide, POI is diagnosed by primary or secondary amenorrhea in women under 40 years of age, elevated follicle stimulating hormone (FSH) serum levels that are akin to levels found in menopausal women with reduced estradiol levels (Nelson, 2009). In addition to a reduced reproductive capacity at an early age, POI has other health consequences including increasing the risk of cardiovascular disease, osteoporosis, anxiety, and depression (Hewlett and Mahalingaiah, 2015). POI is one of the leading causes of female infertility, it is mainly spontaneous in nature, but there is a positive family history in 10%–15% of POI patients. The probability of POI diagnosis increases from 1 in 10,000 before 20 years of age, to 1 in 1000 before 30, to 1 in 100 women before age 40 (Fortuño and Labarta, 2014). Although POI is often sporadic in nature, there are likely complex genetic factors underlying the disorder. Many POI cases can be attributed to X chromosome abnormalities, including X chromosome monosomy called Turner Syndrome. Genes on the X chromosome disproportionately contribute to POI risk. The *Fragile X Mental Retardation 1* (*FMR1*) gene contains CGG triplet repeats that can cause fragile X syndrome if repeat numbers are above 200. However, unaffected mothers of these fragile X individuals, whose CGG repeats range from 55 to 200 have a 13%–26% chance of experiencing POI (Wittenberger et al., 2007; Fortuño and Labarta, 2014). Despite the common trend of the X chromosome and particularly *FMR1* contributing to POI susceptibility, many other factors can also be responsible for POI including many of the genes discussed in this article. Mutations in the oogenesis genes *Nobox* and *Figla* and the meiosis gene *MSH5* have been found in different populations to be associated with POI in women (Fortuño and Labarta, 2014). Future research into POI will likely focus on the additive effects of genetic, environmental and epigenetic factors that together contribute to the demise of the ovarian reserve in POI and other related fertility disorders in women.

Folliculogenesis

Patrick R Hannon and Thomas E Curry, University of Kentucky, Lexington, KY, United States

Introduction

There are two main functions of the ovary, (1) the development of the female gamete (oocyte) for fertilization and the propagation of the species, and (2) the production and secretion of sex steroid hormones that regulate reproductive and nonreproductive health. Both of these critical ovarian functions are controlled by the ovarian follicle, which is the functional unit of the ovary.

The follicle consists of the oocyte, or egg, surrounded by granulosa cells and, at later stages of development, theca cells; both of which are somatic cells that support the oocyte. Follicles undergo several irreversible developmental transitions, and this process of follicular development is known as ovarian folliculogenesis. Follicles form by the breakdown of germ cell nests during fetal development to establish the most immature follicle type, known as the primordial follicle. Females are born with a finite supply of primordial follicles, which constitutes the ovarian reserve and represents a female's reproductive potential. There are, however, controversial reports of egg producing stem cells in women suggesting that these rare cells may have the ability to form oocytes and follicles. By default, primordial follicles are quiescent, but once they are selected to develop via a process called initial recruitment, they become primary follicles. These primary follicles continue to develop to become secondary and tertiary follicles (also known as preantral follicles), as discussed in detail below. Preantral follicles then develop into antral follicles. Most early antral follicles undergo atresia, which is a controlled apoptosis-mediated process of follicle death. However, during the follicular phase of a female's reproductive cycle, a small cohort of antral follicles are rescued from atresia and selected to develop further into preovulatory follicles (also known as Graafian follicles) via a process called cyclic recruitment. These preovulatory follicles are the major producers of estrogens in the female and are the only follicle type that is capable of ovulation. The culmination of folliculogenesis results in rupture of the preovulatory follicle and release of the oocyte during the process of ovulation. The ruptured follicle undergoes dynamic transformation into the corpus luteum, which is a progesterone producing structure needed for pregnancy. Fig. 1 outlines follicles at the different stages of development. Important for human health, defects in folliculogenesis can lead to infertility and primary ovarian insufficiency (POI; also known as premature ovarian failure or premature menopause), which underscores the importance of understanding how folliculogenesis is controlled.

Multidirectional interactions between the oocyte, granulosa cells, theca cells, and the hypothalamic-pituitary axis of the endocrine system are paramount for all of the complex developmental transitions of folliculogenesis. Specifically, the cells within the follicle produce growth and signaling factors that act in an autocrine and paracrine manner to regulate the early stages of folliculogenesis (i.e., initial recruitment). Further, hormones secreted from the hypothalamic-pituitary-ovarian axis act in an endocrine manner to coordinate the later stages of folliculogenesis (i.e., cyclic recruitment). The steps involved in each stage of folliculogenesis are outlined in the detailed sections below.

Fig. 1 Stages of folliculogenesis from the immature primordial follicle to the mature antral follicle. Follicles contain the female germ cell (oocyte) surrounded by somatic cells (granulosa cells and theca cells), and, at later stages of development, a fluid filled space called the antrum. Primordial follicles contain the oocyte surrounded by a single layer of squamous granulosa cells. These follicles develop into primary follicles, which contain the oocyte surrounded by a single layer of cuboidal granulosa cells. Primary follicles develop into preantral follicles (secondary and tertiary follicles), which contain the oocyte surrounded by several layers of granulosa cells and a basement membrane separating these cells from theca cells. Preantral follicles develop into antral follicles, which contain the oocyte surrounded by multiple layers of granulosa cells, the antrum, and a basement membrane separating the granulosa cells from the theca cells. Antral follicles develop further into preovulatory follicles, which are capable of ovulation. Figure modified from (Hannon, P. R., Flaws, J. A. (2015). The effects of phthalates on the ovary. *Frontiers in Endocrinology* 6, 8).

Primordial Follicle Formation

The establishment of the ovarian reserve, or primordial follicle formation, occurs during the later stages of fetal life in the human and during the early postnatal life in the rodent. Prior to this, primordial germ cells, which will give rise to oocytes, migrate during embryonic development from the yolk sac to the genital ridge where the undifferentiated gonad resides. These germ cells, now termed oogonia, massively proliferate via mitosis to a peak of 6–7 million oogonia by the 20th week of gestation in the human, and develop into germ cell nests that contain multiple oogonia surrounded by squamous pregranulosa cells. Once established in the germ cell nests, mitosis of oogonia ceases and meiosis begins. It is here that the oogonia become oocytes, and the oocytes progress through meiosis until they are arrested in the diplotene stage of meiotic prophase I.

Primordial follicle assembly then occurs around the 6–9th month of gestation in the human and around the first few days after birth in the mouse. Primordial follicle assembly occurs via a process called germ cell nest breakdown. This process involves the atretic demise of several of the oocytes contained within the germ cell nests. The interaction of several molecular events that leads to oocyte death causes the remaining oocytes to become associated with a single layer of flattened, squamous granulosa cells, resulting in the formation of the primordial follicle.

Fate of the Follicle

Once the primordial follicle population is established, the follicle is destined to four fates: (1) to remain quiescent for varying lengths of time to constitute the ovarian reserve, (2) to directly undergo atresia, (3) to undergo initial recruitment and eventually ovulate, or (4) to experience the most common fate, which is to undergo initial recruitment but later die via atresia. In fact, greater than 99% of all follicles in the ovary are lost via atresia, meaning < 1% of follicles ovulate. As previously discussed, oogonia numbers peak at approximately 6 million during midgestation. Due to germ cell nest breakdown and primordial follicle formation, the newborn ovary contains about 1 million follicles. Of these, only 200,000 remain at puberty, and only 300 will ovulate. This loss of follicles is because atresia is a dynamic process that occurs throughout the entire life of the female, even during embryonic development. Thus, understanding the mechanisms that control folliculogenesis is imperative because the female's finite supply of follicles is constantly dwindling to the eventual point of exhaustion, which occurs at about 51 years of age in women and is known as menopause.

Initial Recruitment—The Primordial to Primary Transition

Primordial follicle recruitment to the primary follicle stage is the first developmental transition that the follicle can undergo following follicle formation. Although the default fate of the primordial follicle is to remain quiescent and immature, the rate-limiting transition of initial recruitment can occur at any stage of life. In humans, it can occur in utero, prior to puberty, during the female's reproductive lifespan, and through the late stages of the menopausal transition. The first change in the primordial follicle in response to initial recruitment is the transformation of the morphology of the granulosa cells from a squamous to cuboidal shape. The diameter of the oocyte also increases in size, and the oocyte now acquires the zona pellucida, which is a thick membrane surrounding the oocyte that is required for fertilization. Initial recruitment to the primary stage of development is complete when the follicle contains a larger oocyte surrounded by a single layer of cuboidal granulosa cells. This process is the longest in duration for folliculogenesis, in which the completion of initial recruitment is estimated to take over 150 days in the human.

Since the primordial follicle is devoid of gonadotropin receptors and theca cells, initial recruitment is gonadotropin-independent and relies on a balance of ovarian-derived factors that either inhibit or promote primordial follicle recruitment. In fact, in vitro and in vivo studies have shown that primordial follicles develop to the early antral stage in the absence of gonadotropins. Under basal conditions, inhibitory factors keep the follicle in a quiescent state and favor follicle survival. A decrease in the levels/activity of these inhibitory factors in addition to the increase/action of stimulatory factors results in development to the primary follicle stage. These factors originate from the oocyte, the squamous granulosa cells, stromal cells that are precursor theca cells that will later be recruited to the follicle during development, and even cells from more mature follicles. [Table 1](#) contains a list of several of the well-documented intraovarian factors that act to promote or inhibit initial recruitment, some of which will be discussed below.

Phosphatidylinositol 3-Kinase Signaling

The phosphatidylinositol 3-kinase (PI3K) signaling pathway is a regulatory pathway that controls processes such as cell proliferation, survival, migration, metabolism, and even the initial recruitment stage of ovarian folliculogenesis. This signaling pathway contains proteins that drive PI3K signaling (i.e., 3-phosphoinositide dependent protein kinase-1 (PDPK1), mammalian target of rapamycin complex 1 (mTORC1), protein kinase B (AKT), and ribosomal protein s6 (rpS6)), and proteins that inhibit PI3K signaling (i.e., forkhead box O3 (FOXO3), phosphatase and tensin homolog (PTEN), and tuberous sclerosis 1 and 2 (TSC1 and TSC2)). Conditional deletion of *Foxo3a*, *Pten*, *Tsc1*, or *Tsc2* from mouse oocytes results in global activation of all primordial follicles,

Table 1 Intrinsic ovarian factors involved in initial recruitment

Factor	Source	Target of action	Action on initial recruitment
AKT	Oocyte	Oocyte	Promote
bFGF	Oocyte	Granulosa cells, precursor theca cells, and stroma	Promote
BMP4/7	Precursor theca cells	Granulosa cells	Promote
KGF	Precursor theca cells	Granulosa cells, precursor theca cells, and stroma	Promote
Kit	Oocyte (also low levels in precursor theca cells)	Oocyte and precursor theca cells	Promote
Kit ligand	Granulosa cells	Oocyte and precursor theca cells	Promote
LIF	Granulosa cells	Oocyte and granulosa cells	Promote
mTORC1	Oocyte	Oocyte	Promote
PDGF	Oocyte and granulosa cells	Granulosa cells	Promote
AMH	Antral granulosa cells	Primordial follicle	Inhibit
FOXL2	Granulosa cells	Granulosa cells	Inhibit
FOXO3	Oocyte	Oocyte	Inhibit
PTEN	Oocyte	Oocyte	Inhibit
TSC1/2	Oocyte	Oocyte	Inhibit

leading to primary ovarian insufficiency (POI); thus, these inhibitory regulators of PI3K signaling maintain primordial follicle quiescence. In addition, studies indicate that acceleration of primordial follicle recruitment occurs because of over-activation of the PI3K signaling pathway brought about by the unrestricted regulation of stimulatory PI3K factors, such as AKT, mTORC1, PDPK1, and rpS6. Therefore, a basal level of PI3K signaling is needed for oocyte survival, a shift in the balance of signaling favoring the PI3K inhibitory components maintains quiescence, while signaling favoring an increase in stimulatory PI3K proteins promotes primordial follicle recruitment. Of importance, primordial follicles from mouse and human ovarian cortical tissue can be stimulated to undergo initial recruitment with the treatment of a PTEN inhibitor and a PI3K stimulating phosphopeptide. This treatment regimen is currently being investigated as a potential therapeutic option for in vitro activation protocols that are used on cryopreserved ovarian tissue from women that have experienced chemotherapy-induced infertility/POI. The PI3K signaling pathway is perhaps the most well-studied signaling pathway related to early ovarian folliculogenesis, and Fig. 2 is a simplified outline of the signaling cascades that bring about initial recruitment.

Kit and Kit Ligand

One of the receptor tyrosine kinases thought to stimulate PI3K signaling in the ovary is the mast/stem cell growth factor receptor, also known as kit. The kit receptor can be activated by binding to kit ligand (also known as stem cell factor, steel factor, and multipotent growth factor) in its soluble and membrane bound forms. Unlike intracellular PI3K signaling that utilizes factors that are restricted to the oocyte, kit–kit ligand signaling involves the multidirectional coordination between the oocyte and precursor theca cells, that express kit, and the granulosa cells, that produce kit ligand. Mutations of the soluble form of kit ligand in

Fig. 2 Regulation of initial recruitment by the phosphatidylinositol 3-kinase (PI3K) signaling pathway. Growth factor-mediated binding to receptor tyrosine kinases recruits PI3K to the inner oocyte membrane, which stimulates the conversion of PIP2–PIP3. PIP3 phosphorylates AKT, while PTEN inhibits PIP3-mediated AKT phosphorylation by converting PIP3 back to PIP2. Phosphorylated AKT can phosphorylate FOXO3, which exports FOXO3 from the oocyte nucleus leading to primordial follicle recruitment. Phosphorylated AKT can also phosphorylate TSC1/2, which destabilizes the protein leading to activation of the mTORC1 cascade and ultimately protein translation and primordial follicle recruitment. Proteins in green are stimulators of initial recruitment, while proteins in red are inhibitors of initial recruitment.

mice arrests follicle development at the primary follicle stage, and neonatal mice treated with a neutralizing antibody for kit disturbs initial follicle recruitment. Previous studies have suggested that granulosa cell derived kit ligand can bind to kit on stromal precursor theca cells to induce their transition into theca cells, promote their migration to become closely associated to the follicle, and initiate proliferation of these soon to be theca cells. Simultaneously, kit ligand has been shown to bind to kit on the primordial follicle oocyte to initiate oocyte growth and development. Of importance, treatment with kit ligand to neonatal rodent ovaries increased the percentage of growing follicles, further suggesting that kit–kit ligand signaling may be a potential mediator of initial recruitment.

Other Stimulatory Factors

Similar to treatment with kit ligand, rat ovary cultures treated with basic fibroblast growth factor (bFGF), leukemia inhibitory factor (LIF), keratinocyte growth factor (KGF), bone morphogenetic proteins 4 and 7 (BMP4 and BMP7), and platelet-derived growth factor (PDGF) exhibited a dramatic increase in initial recruitment, as evident by a decrease in primordial follicle numbers and an increase in growing follicle numbers. Further, blocking bFGF and LIF action with neutralizing antibodies caused a reduction in primordial follicle activation. Following binding to its receptors located on granulosa cells, precursor theca cells, and stroma cells, bFGF appears to regulate granulosa, theca, and stromal cell growth. LIF produced by the granulosa cells is thought to act upon both the granulosa cells and the oocyte to initiate oocyte growth and the recruitment of precursor theca cells to the follicle. KGF is found in newly recruited precursor theca cells that are in contact with the squamous granulosa cells surrounding the primordial follicle and is thought to act upon the granulosa cells to initiate proliferation, the change to cuboidal morphology, or the upregulation of kit ligand. BMP4, localized to precursor theca cells, and BMP7, localized to theca cells of more developed follicles, also stimulate initial recruitment. Further, BMP4 has been shown to aid in the survival of primordial follicle oocytes, as treatment with a neutralizing antibody to BMP4 resulted in atresia of all the oocytes in a rat ovary culture system. PDGF expressed in oocytes, and granulosa cells to a lesser degree, acts on granulosa cells to potentially increase kit ligand levels for primordial follicle activation.

Anti-Müllerian Hormone

Anti-Müllerian hormone (AMH) belongs to the transforming growth factor beta (TGF- β) superfamily and is involved in the inhibition of initial recruitment. Although the mechanism by which AMH suppresses initial recruitment is largely unknown, AMH is recognized as a paracrine factor secreted from maturing follicles that maintains primordial follicle quiescence. Primordial follicles do not express AMH, and controversy exists whether they express receptors for AMH; however, follicular AMH levels that are produced by granulosa cells begin to rise after the follicle is initiated to develop. The highest levels of follicular AMH are present in the preantral and early antral follicle stages before declining again with preovulatory follicle development. *Amh* knockout mice exhibited depletion of the primordial follicle reserve as these mice aged, albeit much slower than that of *Pten* knockout mice. Further, treatment with AMH in vitro in human and rodent ovarian samples resulted in an increase in the number of primordial follicles with a subsequent decline in the number of growing follicles. Serum AMH levels are also used clinically to assess ovarian function, primarily because serum levels do not fluctuate during a female's menstrual cycle. In accordance with follicle development and the dwindling supply of follicles with age, serum AMH is highest at puberty when the number of maturing follicles is high and decreases with age until it is negligible at menopause when the ovary is devoid of follicles. Since the production of AMH is highest in the early antral follicle, serum AMH levels are predictive of the number of antral follicles that can be stimulated by gonadotropins and, consequently, of in vitro fertilization outcomes. Important for initial recruitment, there is also a positive correlation between serum AMH levels and the number of primordial follicles present in the ovary. This is because AMH is thought to be a regulator of the status of the female's ovarian reserve. Thus, AMH is increasingly being used to assess a woman's fertility and potential reproductive lifespan.

Forkhead Box L2

Forkhead box L2 (FOXL2) is a wing-helix/forkhead transcription factor that has been shown to be a negative regulator of initial primordial follicle recruitment. FOXL2 is expressed in granulosa cells from the primordial follicle and throughout several stages of folliculogenesis. Results obtained from *Foxl2* knockout mice suggest that FOXL2 plays a critical role in the development of granulosa cells within primordial follicles. Specifically, these mice exhibited premature growth/development of oocytes that resemble oocytes of more mature follicles. However, these changes in the oocyte occur in the absence of the squamous to cuboidal granulosa cell transition. The entire follicle pool then undergoes atresia because the oocyte and somatic cells must develop simultaneously. Due to this POI, these mice are infertile. Thus, FOXL2 appears to mediate the squamous to cuboidal transition and proliferation of granulosa cells, which are required steps in initial recruitment. Importantly, sequences of the *FOXL2* gene are highly conserved across species, and mutations of the *FOXL2* gene in humans cause Blepharophimosis, ptosis, and epicanthus inversus syndrome (BPES). Females with BPES type I are at a high risk of POI-induced infertility, which underscores the potential importance of this inhibitory factor of folliculogenesis in humans.

Initial Recruitment—Summary

Contrary to cyclic recruitment that occurs during the follicular phase of a female's reproductive cycle, the molecular mechanisms that control initial recruitment are poorly understood. Although the list of factors involved in initial recruitment within this article is not exhaustive, it should be emphasized that primordial follicle recruitment is a complex, multidirectional process involving several cell types and signaling molecules that converge on multiple signaling pathways. It is likely that the intricate coordination between these stimulatory and inhibitory substances determines a primordial follicle's fate of survival, quiescence, or recruitment.

Transitions From the Primary Stage to the Early Antral Stage

Once established, primary follicles are devoid of theca cells, but precursor theca cells derived from ovarian stroma have already begun migrating to the follicle as early as the final stages of initial recruitment. The granulosa cells contained in a single layer in the primary follicle undergo mitosis and multiple layers of granulosa cells that are capable of producing steroids form, establishing the preantral follicle. It takes roughly 120 days for this process to occur in the human.

Once the follicle has reached the preantral stage, a basement membrane and two layers of theca cells form. The theca interna is the inner layer of cells that are adjacent to the basement membrane separating the theca cells from the granulosa cells and are steroid producing cells. The theca externa is the outer layer of cells comprised predominantly of nonsteroidogenic fibroblast-like cells that become part of a collagenous connective tissue. Vascularization of the theca cells provides the follicle with direct access to the bloodstream, and thus access to nutrients and hormones, such as gonadotropins.

As the follicle develops further, granulosa cells continue to proliferate forming additional layers and theca cell vascularization increases. The substances brought in through the bloodstream and the secretory products produced by the proliferating granulosa cells result in the formation of fluid-filled spaces within the granulosa cell layer. These spaces eventually coalesce to form a singular fluid cavity within the granulosa cell layer, which is known as the antrum, or antral cavity. Following the initial appearance of the antral spaces, the follicle is called an early antral follicle. This process occurs over a span of roughly 70 days in the human.

Similar to initial recruitment, the transitions from the primary stage to the early antral stage are largely driven by intraovarian factors and signaling pathways. This is confirmed by the evidence that early antral follicles are formed in the complete absence of gonadotropins. Some of the intraovarian factors that control these transitions are presented in **Table 2**. However, some studies suggest that gonadotropins may help mediate follicle development during these stages. Specifically, theca cells contain luteinizing hormone (LH) receptors, and granulosa cells contain follicle-stimulating hormone (FSH) receptors at early stages of development. Thus, the middle transitions of folliculogenesis are not entirely gonadotropin-independent like initial recruitment, but rather, these transitions appear to be gonadotropin-responsive.

Cyclic Recruitment—The Early Antral to Preovulatory Transition

To this point in folliculogenesis, the ovary now contains a cohort of early antral follicles that are gonadotropin responsive and able to be further stimulated by FSH for final maturation to the preovulatory stage. Hormonal feedback loops that exist within the

Table 2 Intrinsic ovarian factors involved in preantral/early antral follicle development

<i>Factor</i>	<i>Source</i>	<i>Action</i>
Activins	Granulosa cells	Stimulate granulosa cell proliferation
AMH	Granulosa cells	Inhibitory factor on small follicle development
BMP15	Oocyte	Stimulate granulosa cell proliferation
BMP4/7	Theca cells	Modulate FSH signaling to increase estradiol levels, prevent premature luteinization
Connexins 37 and 43	Granulosa cells and granulosa-oocyte junction	Communication between granulosa cells to granulosa cells and oocyte to granulosa cells. Knockouts have inhibited development beyond primary stage
Cyclin D2	Granulosa cells	FSH stimulated factor that controls granulosa cell proliferation
GDF9	Oocyte	Theca cell recruitment. Knockouts have inhibited development beyond primary stage
Hedgehog signaling members	Granulosa cells and theca cells	Proper theca cell function
IGF1/IGFR	Granulosa cells	Enhance granulosa cell responsiveness to FSH
KGF	Theca cells	Modulating communication between theca cells and granulosa cells
Kit/kit ligand	Granulosa cells and oocyte	Continued follicle development, oocyte growth, and theca cell organization
NTF5/BDNF/NTRK2	Granulosa cells and oocyte	Knockouts have impaired development beyond primary stage
WT1	Granulosa cells	Inhibitory factor on small follicle development

IGF1, insulin-like growth factor 1; IGFR, insulin-like growth factor receptor; NTF5, neurotrophin 5; BDNF, brain-derived neurotrophic factor; NTRK2, neurotrophic tyrosine kinase receptor type 2; WT1, Wilms tumor 1.

hypothalamic-pituitary-ovarian axis lead to the fluctuation of FSH levels during the menstrual and estrous cycles. The rising level of FSH during the late luteal/early follicular stages of the menstrual/estrous cycle is undeniably the most important catalyst for preovulatory follicle development. Without FSH stimulation, the early antral follicle undergoes atresia, and in fact, early antral follicles are the most susceptible to atretic demise. Thus, further development at this stage is now gonadotropin-dependent. Since the pattern of FSH secretion is cyclical, and FSH is the predominant factor in antral follicle development and survival, this period of folliculogenesis is referred to as cyclic recruitment. This development is the most rapid and occurs during the follicular phase of the menstrual cycle, or about 14–20 days.

Physical characteristics of cyclic recruitment include the coalescence of antral spaces of the early antral follicle to form a singular antral cavity. As theca cell vascularization continues to increase, so does the size of the antrum. This is accompanied by FSH-mediated mitosis of granulosa cells, all of which leads to a massive increase in the size of the maturing antral follicle over a very short period of time. As the antrum increases in size, different subpopulations of granulosa cells emerge. This is largely driven by a concentration gradient of oocyte-derived growth differentiating factor 9 (GDF9) and bone morphogenetic protein 15 (BMP15) that diminishes with distance from the oocyte. The mural granulosa cells are the outermost cells surrounding the basement membrane and are the most steroidogenically active, estradiol-producing cells. The cumulus granulosa cells surround the oocyte to promote its growth and developmental competence. These two subpopulations of granulosa cells respond differently to gonadotropins but both are needed for successful ovulation.

Maturing antral follicles are major producers of sex steroid hormones in the female, and these hormones (namely estradiol) are required for further follicle development. Steroidogenesis requires both follicular somatic cell types and both gonadotropins from the anterior pituitary; thus, this process is called the two-cell, two-gonadotropin hypothesis (Fig. 3). Theca cells produce androgens under the control of LH signaling, but they lack the ability to synthesize estrogens, such as estradiol. Granulosa cells produce estradiol under the regulation of FSH signaling, but they lack the ability to synthesize androgens. Both of these cell types and gonadotropins are needed for ovarian steroidogenesis as theca cells provide precursor androgens, which are converted to estradiol in the granulosa cells by an enzyme called aromatase. Estradiol production is largely driven by FSH signaling, as FSH increases the levels of aromatase in granulosa cells. Although granulosa cells are initially devoid of LH receptors, both FSH and estradiol signaling lead to the acquisition of LH receptors on the granulosa cells, which is required for ovulation.

Fig. 3 The two-cell, two-gonadotropin hypothesis of ovarian steroidogenesis. Theca cells contain luteinizing hormone (LH) receptors (LHCGR). Under the action of LH signaling, cholesterol is converted to androgens via several enzymatic reactions in the theca cells. These androgens can diffuse through the basement membrane to the granulosa cells. Granulosa cells contain follicle-stimulating hormone (FSH) receptors (FSHR). Under the action of FSH signaling, aromatase is dramatically increased, which is the enzyme that converts androgens to estrogens, such as estradiol. Estradiol can then act within the follicle or can be released in circulation to act throughout the body. The theca cells lack the enzymes required to synthesize estradiol, and granulosa cells lack the enzymes to synthesize androgens. Thus, both cell types and gonadotropins are required for ovarian steroidogenesis.

As stated, cyclic recruitment corresponds to the cyclic hormonal patterns of the menstrual/estrous cycle and leads to the development of a dominant follicle(s), depending on the species, that will be selected to ovulate. Increasing FSH levels give rise to maturing antral follicles, and thus increasing estradiol levels. Insulin-like growth factors and activin A have also been shown to facilitate the increase in estradiol levels during this period. Estradiol, in turn, negatively feeds back to the hypothalamic-pituitary axis causing a decrease in FSH levels. This is also accomplished by the action of inhibin B, which is a granulosa cell-produced peptide hormone that inhibits the anterior pituitary from producing and secreting FSH. As this is occurring, a dominant preovulatory follicle(s) continues to grow and diverges from subordinate antral follicles within the cohort. Since FSH is the predominant survival factor for the antral follicle, a decrease in FSH leads to atresia of the subordinate follicles. The dominant follicle escapes this demise because it is more sensitive to and more efficiently utilizes gonadotropins, possibly due to increased granulosa cell numbers, FSH and LH receptors, and vasculature supply, thereby providing mechanisms to thrive in the dwindling FSH environment. As such, the dominant antral follicle selected to ovulate further enhances its dominance by creating a hormonal milieu that inhibits, both directly and indirectly, the development of subordinate antral follicles. This, accompanied by the increase in granulosa cell-derived LH receptors, ensures a fail-safe mechanism for ovulation.

The dominant follicle is now producing threshold levels of estradiol that positively feedback to the hypothalamic-pituitary axis initiating the ovulatory LH surge. The rapid rise in LH induces a cascade of events in the follicle, including meiotic resumption in the oocyte, cumulus granulosa cell expansion, breakdown of the follicular wall, and differentiation of follicular cells to luteal cells. These events lead to ovulation and the transformation of the follicle into the corpus luteum. The periovulatory period, or the time between the LH surge and oocyte release, varies across species from 12 to 18 h in rodents to 36 h in humans and nonhuman primates.

Fig. 4 Progression and regulation of ovarian folliculogenesis. The finite supply of primordial follicles remains quiescent under the action of intraovarian inhibitory factors. A decrease in these factors and/or an increase in intraovarian stimulatory factors leads to primordial follicle activation to the primary stage of development. This process is gonadotropin-independent and is known as initial recruitment. Primary follicles develop into preantral and early antral follicles via the action of intraovarian factors and gonadotropins. These follicles are the most susceptible to atresia, or follicle death. Select antral follicles are rescued from atresia by responding to the cyclic changes in FSH secretion, and they become preovulatory follicles that are capable of oocyte release and corpora lutea formation. This final stage of development is gonadotropin-dependent and is known as cyclic recruitment. Figure modified from (Hsueh, A. J. W., Kawamura, K., Cheng, Y., Fauser, B. C. J. M. (2015). Intraovarian control of early folliculogenesis. *Endocrine Reviews* 36(1), 1–24; (McGee, E. A. and Hsueh, A. J. W. (2000). Conclusion

Folliculogenesis, from primordial follicle activation to the culmination of ovulation, is a complex and dynamic ovarian process involving multiple ovarian and endocrine cells and numerous signals that takes about 1 year in the human (Fig. 4). Folliculogenesis is essential for ovarian function and the propagation of the species because it allows for ovulation and the synthesis of the vital sex steroid hormones estradiol and progesterone. Thus, understanding how folliculogenesis is controlled and regulated is crucial for women's reproductive health. Primarily, this is because defects in folliculogenesis have been shown to cause infertility and POI. Infertility and POI negatively impact a woman's physical and mental state and has potential dire economic impacts. Elucidating the mechanisms that control all stages of folliculogenesis will greatly benefit patients that are diagnosed with ovarian-derived fertility defects. These include infertile women, women of advanced maternal age, women that are poor responders to conventional infertility treatments, women with a low ovarian reserve, prepubertal cancer patients undergoing chemotherapeutic treatments that inadvertently target and deplete the finite supply of primordial follicles, and women that have other ovarian disorders such as polycystic ovary syndrome. Therapeutic manipulations of folliculogenesis are being used as novel assisted reproductive technologies (ART) in these female patients. These include in vitro fertilization protocols, activation protocols for immature oocytes for in vitro fertilization, activation of immature follicles from cryopreserved ovarian tissues either in vitro or following transplantation, and bioengineering synthetic ovarian tissue.

Antral Follicles: Recruitment and Selection of Ovulatory Follicles

Joanne E Fortune, Cornell University, Ithaca, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

The pace of ovarian follicular development is extremely slow. For example, development from the primordial to the preovulatory stage is estimated to take about 6 weeks in rats, about 6 months in cattle, and up to a year in humans (reviewed in Fortune, 1994). Follicles spend most of that time traversing the preantral stages (primordial, primary, and secondary). When a certain number of granulosa cells layers have formed, fluid-filled spaces begin to appear within the granulosa cell/oocyte compartment of the follicle. The spaces gradually enlarge and coalesce into the follicular antrum. The granulosa cells differentiate into mural granulosa cells, lining the basement membrane and cumulus granulosa cells, which surround the oocyte and develop special structural and functional relationships with it (Fig. 1). Mammalian follicles become antral at a diameter of 0.2–0.4 mm.

The mechanisms of antrum formation and the role of the antrum and its follicular fluid are far from completely understood (see reviews by Rodgers and Irving-Rodgers, 2010; Hirshfield, 1991). No capillaries penetrate the basement membrane and it has been hypothesized that formation and progressive enlargement of the antrum serves to keep all the mural granulosa cells close to the vascularized thecal compartment of the follicle as the number of granulosa cells increases and thereby, facilitates their access to components of blood such as oxygen, nutrients, and hormones. In species like mice and rats, which ovulate when follicles are about 0.5 or 1 mm in diameter, respectively, follicular growth is almost complete when the antrum forms and the oocyte has completed its development and can resume meiosis if it is released from the follicle. In other species, considerable increases in size occur during the antral phase of follicular development to produce much larger ovulatory follicles (e.g., ~15 mm in humans and cattle, ~7–8 mm in sheep and pigs, 40–45 mm in horses) and oocyte development may continue during the early antral phase. Fig. 1 represents a small antral follicle; in species with large ovulatory follicles, the follicular fluid comprises a much larger percentage of the follicular volume than in small follicles. The follicular fluid provides the microenvironment of the granulosa cells and oocyte and it comprises an increasingly greater proportion of the follicular volume as follicular diameter increases. In some ways its composition is similar to blood plasma, but some components of the follicular fluid are present in dramatically different concentrations vs. their concentrations in the general circulation, especially in preovulatory follicles. Thus, the granulosa cells and oocyte can be regulated both by compounds in the general circulation that diffuse across the basement membrane from the thecal layer and also by components of the follicular fluid, i.e., by their microenvironment.

The “job” of antral follicles is (1) to nurture the oocyte and maintain or facilitate its meiotic and developmental capacities and (2) to grow to a size with enough theca and granulosa cells to produce sufficient androgen precursor (theca) to enable granulosa cells to secrete enough estradiol to trigger the surge release of gonadotropins from the anterior pituitary gland and thereby stimulate ovulation. Many follicles enter the antral stage of development, but only a very few complete it by ovulating. Although atresia (programmed death) of follicles occurs at every stage of follicular development, atresia does not occur evenly across the follicular stages. Analysis of patterns of atresia in several species has revealed that the rate of atresia is highest late in antral follicular development. A careful analysis by Hirshfield (1991) of the course of follicular development in rats revealed that atresia is most prevalent during the “penultimate” stage of follicular development, i.e., the stage just before they might enter the pool of potentially ovulatory follicles (Fig. 2). A study by Gougeon of the course of human follicular development and data for follicular development in cattle showed that in both species the highest percentages of atretic follicles are observed late in follicular development (~4–10 mm diameter) (reviewed in Fortune, 1994).

Fig. 1 Schematic diagram of a cross section through a mammalian antral follicle, showing the oocyte and surrounding cumulus cells, follicular antrum, granulosa cells, theca cells, and thecal blood vessels. The size of preovulatory follicles varies greatly in different mammalian species (from ~0.5 to ~45 mm in diameter). The antrum comprises an increasingly greater proportion of the follicle as follicular size increases.

Fig. 2 Schematic representation of the temporal progression of follicular growth in rats, showing that the initial stages of follicular development occur much more slowly than the final stages and that most atresia occurs during a few granulosa cell generations. The numbers and filled circles above the line indicate granulosa cell generations (time required for doubling of granulosa cells in the largest cross section through the follicle). GC, granulosa cell; CL, corpus luteum. Reprinted, with permission, from Fortune, J.E. (1994). Ovarian follicular growth and development in mammals. *Biology of Reproduction* 50, 225–232; figure provided by Dr. A.N. Hirshfield.

Taken together, these observations suggest that many antral follicles reach a particular, species-specific size at which atresia is their normal fate. It is as though they run into a brick wall or reach a closed door and can develop no further. In more scientific terms, it seems likely that basal hormonal conditions (gonadotropin concentrations) are sufficient to sustain follicular growth to a certain, species-specific size and in the absence of some additional endocrine signal, regression ensues. This article is focused on the patterns of development of follicles that survive beyond this point of natural follicular death and the mechanisms that allow some follicles to develop beyond the usual end of follicular life and even, in some cases, to ovulate. During reproductive cycles one or more groups (depending on the species) of antral follicles are recruited to grow larger than most antral follicles and then, from the follicles of the recruited cohorts, a species-specific number of follicles is selected for further development and potential for ovulation. The patterns of follicular development in various species and the mechanisms that subserve follicular recruitment and selection for dominance are reviewed in this article. This topic is of practical interest because understanding these mechanisms has been (and will be) important for the development of interventions to subvert the natural regulatory mechanisms, such as superovulation of domestic animals and hormonal stimulation of women prior to in vitro fertilization.

Patterns of Follicular Development and Regression

Follicular development is by its nature a dynamic process, but careful histological analysis can reveal temporal patterns and in some species serial rectal or vaginal palpation of the ovaries can detect changes in large structures over time (large follicles or corpora lutea). A more direct tool for assessing changes in ovarian structures over time, ovarian ultrasonography, became available in the 1980's. In species with fairly large ovulatory follicles, the final stages of follicular development have been visualized by trans-rectal, trans-vaginal, and/or trans-abdominal ultrasonography. The fluid-filled follicular antrum absorbs ultrasound waves and appears as a black spherical space which can be measured to estimate follicular diameter. In contrast to histology, ultrasonography allows repeated visualization of individual follicles in the same animal (or person) over time and their growth and/or demise can thus be followed.

Studies of the dynamics of antral follicular development by histology or ultrasonography revealed that follicles above a certain species-specific size (the size when follicles naturally die) do not appear at random during reproductive cycles. Rather there are specific times when a group of follicles contemporaneously grows larger than normal. This is referred to as "follicular recruitment" or sometimes as "cyclic recruitment" by authors who consider the activation of primordial follicles to begin growth as "initial recruitment". Recruitment of follicular cohorts or "waves" is most obvious in species with large preovulatory follicles, where individual follicles can be followed over time with ultrasonography (cattle and other large ruminants, horses, humans), but it can be deduced by careful histological analyses of the ovaries of species with smaller preovulatory follicles.

These studies have revealed several different patterns. Cattle have been studied extensively because the large size of their ovulatory follicles, the position of their ovaries within the abdominal cavity, and their availability make them excellent candidates for serial transrectal ultrasonography. Ultrasonography revealed that large, ovulatory-size follicles do not appear continuously or at random during the bovine estrous cycle (as some researchers had hypothesized), but rather cohorts of follicles are recruited to grow larger than normal two or three times during the cycle, about every 7–10 days (reviewed in Fortune, 1994; Ginther et al., 2001). The follicles in each wave increase in size for several days and then one follicle is "selected" for further growth (the dominant follicle), whereas the other (subordinate) follicles stop growing and begin to regress. The dominant follicle of the final wave of the cycle (second or third) ovulates (Fig. 3A). It is interesting that similar, but always nonovulatory, follicular waves occur in heifers during the prepubertal period and during pregnancy (reviewed in Fortune, 1994). The wave-like pattern seems to be inherent to the bovine ovary after a certain age. Sheep display a similar pattern of multiple waves throughout the cycle, but they are less regular than in cattle; there can be 2–6 follicular waves per cycle and ovulation of the dominant follicles of both the final and penultimate waves has been observed (reviewed in Goodman and Inskeep, 2015; Scaramuzzi et al., 2011). It is more difficult to study follicular

Fig. 3 Schematic diagrams of three patterns of follicular development during mammalian reproductive cycles. The *lines* represent changes in follicular diameter as follicles grow or regress; the asterisks denote ovulation. Panel A depicts a pattern observed in cattle and sheep, in which dominant, ovulatory-size follicles develop throughout the estrous cycle. Panel B shows a pattern typical of species such as rats and pigs, with dominant follicles developing only during the follicular phase. Panel C shows a pattern observed in horses and humans, with a minor wave of follicular development (dominant follicle smaller than ovulatory size) during the luteal phase.

dynamics in litter-bearing species like rodents and pigs, but it appears that follicles are recruited for potential ovulation during the follicular phase and then a subset of the recruited follicles is selected for dominance and ovulation (**Fig. 3B**) (reviewed in [Fortune, 1994](#); [Guthrie, 2005](#); [Soede et al., 2011](#)).

Initially, it was reported that ovulatory follicles of humans and nonhuman primates such as rhesus monkeys develop during a single wave of follicular recruitment and selection during the follicular phase of the cycle (reviewed in [Fortune, 1994](#)). More recent and very careful ultrasonographic analyses of follicular development during human menstrual cycles revealed the presence of one or two “minor” waves of follicular development during the luteal phase in most women studied and an occasional minor wave during the follicular phase (in women with long follicular phases) (**Fig. 3C**) (reviewed in [Baerwald et al., 2012](#)). The dominant follicle of the minor waves is generally smaller than the preovulatory follicle that develops during the ovulatory wave of the follicular phase (**Fig. 3C**). Mares have a similar pattern of follicular development, with some, but not all, mares exhibiting a wave of follicular development during the luteal phase with a dominant follicle smaller than ovulatory size (a minor wave) (reviewed in [Ginther et al., 2001](#); [Baerwald et al., 2012](#)). It is not clear whether nonhuman primates also have minor waves; their follicles are smaller than human follicles and thus much harder to visualize by ultrasonography. The mechanisms that regulate these follicular patterns are discussed in the sections below.

Recruitment of Follicles Into Follicular Waves (Cohorts)

A common pattern of recruitment of a wave or cohort of follicles at a species-specific diameter has been documented, as discussed above. But what causes groups of follicles to grow synchronously beyond the stage when most follicles become atretic and why do some species have several waves of follicular development per reproductive cycle, whereas only one cohort is recruited in others? In species in which this question has been examined carefully, a small rise in circulating FSH accompanies the initiation of each follicular wave (reviewed in [Baerwald et al., 2012](#); [Fortune et al., 2001](#); [Fortune, 1994](#); [Ginther et al., 2001](#); [Mihm and Evans, 2008](#)). In primates and pigs, circulating FSH is slightly higher at the beginning of the follicular phase than during the mid-luteal or mid to late follicular phases. Rats have a secondary surge of FSH on the day of estrus, preceding recruitment of the next cohort of ovulatory follicles. Cattle also exhibit a secondary surge of FSH around the time that the first follicular wave of the cycle begins and small rises in FSH were detected just prior to the later follicular waves of the estrous cycle. It is not clear if the minor waves during the luteal phase in women are preceded by an increase in FSH. The differing patterns of follicular wave dynamics during the luteal phase in different species may be due to the extent to which their corpora lutea secrete feedback inhibitors of FSH (estradiol, inhibin) and/or to differing sensitivities to such feedback.

The temporal relationships between increases in circulating FSH and the initiation of follicular waves that have been documented in a number of species suggest that the two events are causally related (see **Fig. 4**). Indeed, the hypothesis of a cause and effect relationship is supported by the results of experiments in which the elevation in FSH was suppressed, mimicked, or enhanced. For example, in cattle a secondary surge of FSH occurs about 1 day after the LH/FSH surge and injection of bovine follicular fluid (containing inhibin which suppresses FSH) delayed the first wave of follicular development for the duration of the suppression of FSH. Similar experiments with rats provided evidence that the secondary surge of FSH in that species prevents the recruitment of the next cohort of ovulatory follicles. When LH was held constant in cynomolgus monkeys and plasma FSH was gradually increased in a manner designed to mimic the early follicular phase, increases in circulating estradiol provided evidence that the small increase in FSH had allowed follicles to develop beyond the stage when they would normally become atretic ([Zelevnik and Kubik, 1986](#)). In addition, treating animals or women with exogenous FSH increases the number of follicles recruited and has been used to superovulate domestic animals and promote the development of multiple ovulatory follicles in women. The critical role of FSH in recruitment of follicles into waves appears to be well established and has been reviewed in more detail by [Baerwald et al. \(2012\)](#), [Fortune et al. \(2001\)](#), [Fortune \(1994\)](#), and [Ginther et al. \(2001\)](#).

Fig. 4 FSH threshold/window concept. Schematic depiction of the intercycle rise in FSH during the human menstrual cycle that recruits a cohort of follicles for growth during the early follicular phase. The number of follicles recruited and selected for dominance depends on width of the “window,” the time when FSH is elevated above the threshold level. Figure modified from Macklon, N.S. and Fauser, B.C. (1998). Follicle development during the normal menstrual cycle. *Maturitas* 30(2), 181–188 with permission from Elsevier.

Selection of Dominant (Ovulatory) Follicles

Introduction

The number of follicles recruited into waves is typically greater than the number of follicles that ovulate. During waves of follicular development only some of the recruited follicles (a species-specific number) continue growth towards ovulatory status (Fig. 3). How the dominant follicle(s) is selected for dominance, exerts and maintains dominance, and loses dominance (in species with multiple follicular waves) has been the focus of numerous studies. The key characteristic of dominant follicles is their greater capacity to secrete estradiol, compared with their sister subordinate follicles. Secretion of increasingly greater quantities of estradiol is the hallmark of preovulatory follicles. Dominant follicles already have a higher capacity for estradiol production at the time when their growth trajectory diverges from that of the subordinate follicles (reviewed in Fortune et al., 2001; Ginther et al., 2001) and estradiol is a negative feedback regulator of FSH. This suggests that they may “beat back” the subordinate follicles by reducing FSH to levels insufficient to sustain continued growth of the subordinate follicles. However, this hypothesis assumes that dominant follicles can continue their development with levels of circulating FSH insufficient for growth of subordinate follicles. The experiments with cynomolgus monkeys mentioned above showed that estradiol continued to increase after the level of circulating FSH was progressively reduced (Zelevnik and Kubik, 1986), which implies that once dominant follicles have been selected they can continue to develop and secrete estradiol in an environment of lower FSH.

Cattle have been a useful model in efforts to understand how the dominant follicle is selected and they provide an excellent animal model for human follicular development (Campbell et al., 2003). They are more available for experimental manipulation *in vivo* than nonhuman primates and their dominant and subordinate follicles are large enough to be visualized by ultrasonography and to be removed for analysis of follicular characteristics (follicular fluid hormones, levels of mRNA in follicular cells, etc.) and/or for culture of follicular cells. The dominant follicle of bovine nonovulatory waves can ovulate if the corpus luteum is regressed by injection of prostaglandin F_{2α} (PGF_{2α}) during the follicle’s tenure as dominant follicle (Fortune et al., 1991), indicating that all dominant follicles of the cycle have full developmental potential if the right endocrine environment is present. The first wave of follicular development of the bovine estrous cycle is a particularly useful model because it begins at a predictable time of the cycle, i.e., following ovulation of the previous dominant follicle. Hence much of the literature reviewed below is based on studies with cattle.

Characteristics of Dominant Follicles

At first, attempts to understand how follicles are selected in cattle were focused on describing the characteristics of dominant vs. subordinate follicles at various stages of the first follicular wave (reviewed in Fortune et al., 2001; Ginther et al., 2001). Estradiol concentrations in the follicular fluid and estradiol secretion by follicular wall tissue were the only characteristics examined that were different (higher) in the dominant follicle than in the largest subordinate follicle at a time when the dominant follicle had just reached a significantly larger diameter. It makes sense that estradiol production is a key characteristic of emerging dominant follicles because estradiol can exert negative feedback on FSH secretion by the anterior pituitary, depriving the subordinate follicles of sufficient FSH for their further growth and development.

Ovarian follicles produce estradiol via interactions between their two endocrine cell types, the inner granulosa cells, which line the antrum of the follicle, and the outer theca cells, which lie outside the basement membrane between the theca and granulosa cells (Fig. 1). From very early stages of follicular development, theca cells have LH receptors and granulosa cells have FSH receptors. Theca cells are stimulated by LH to convert cholesterol to progesterins and hence to androgens, but they lack the aromatase enzyme necessary to convert androgens to estrogens (estradiol and estrone). The granulosa cells cannot synthesize androgens, but they can convert androgens that diffuse from the theca across the basement membrane to estrogens, primarily in the form of estradiol.

Granulosa cells also acquire LH receptors as follicles develop towards ovulation. Comparisons of levels of mRNA for LH receptor, FSH receptor, aromatase, and P450 17 α -hydroxylase in follicular cells of the dominant vs. the largest subordinate follicle revealed that they were all higher in the dominant follicle, but not until a day after the difference in estradiol was detected. Therefore, a number of differences were detected, but all of them followed selection for dominance (Fortune et al., 2001). However, it seems logical that biochemical/molecular changes in the future dominant follicle, before it can be detected as significantly larger in diameter, allow it to grow a little faster and to begin to make more estradiol than its sister subordinate follicles and thus achieve morphological (size) dominance.

Role of the Insulin-Like Growth Factor (IGF) System in Selection of Follicles for Dominance

Studies of the characteristics of dominant follicles summarized above revealed that they have a greater capacity to produce estradiol when they are first detected as significantly larger in diameter than other follicles of the wave. Mechanisms that enable this capacity must precede, and facilitate, their selection for dominance. There is evidence for cattle that changes in the insulin-like growth factor (IGF) system in the future dominant follicle (i.e., before divergence in follicular size) enable increased production of estradiol (reviewed in Ginther et al., 2001; Fortune et al., 2001; Mihm and Evans, 2008; Spicer, 2004). The IGF system comprises two ligands (IGF-I and -II), two receptors (types 1 and 2), and six IGF binding proteins (IGFBP-1 through -6). In mice, IGF is essential for follicular development beyond the late preantral/early antral stage and numerous effects of IGF on follicular function have been documented. Effects of IGF on follicle cells are inhibited by low molecular weight IGFBPs (-2, -4, and -5) because they bind IGF and prevent it from binding to its receptor. Specific IGFBP proteases can cleave IGFBPs, thus freeing IGF to bind to its receptor.

In bovine follicles, FSH induces the IGFBP-4/-5 protease PAPP-A (pregnancy-associated plasma protein A), suggesting that changes in PAPP-A might be important in selection of follicles for dominance. To test that hypothesis, follicles of the first follicular wave of the bovine estrous cycle were isolated before and after the dominant follicle could be detected by a larger diameter; the follicular fluid was collected and measured for concentrations of estradiol and free IGF-1 and abundance of IGFBP-2, -4, and -5 and PAPP-A (reviewed in Fortune et al., 2004). The results supported the conclusion that, of the follicular components examined, an increase in PAPP-A was the earliest change, followed by a decrease in IGFBP-4 and -5 and an increase in free IGF-1, and then an increase in estradiol (Fig. 5). Thus, biochemical changes were detected in one follicle of the cohorts before size deviation, suggesting that the dominant follicle is selected biochemically (functionally) prior to size deviation. Since IGF synergizes with FSH to increase estradiol production, the increase in free IGF (due to the increase in PAPP-A) in one follicle of the wave would allow that follicle to ramp up its production of estradiol very quickly, rapidly suppressing basal FSH to levels insufficient to support similar developmental changes in other follicles of the cohort. This postulated involvement of the IGF system in selection for dominance is further supported by experiments in vivo showing that increasing circulating FSH slightly promotes the development of co-dominant follicles, both of them with higher PAPP-A than in subordinates. In addition, a low level of IGFBP-4 in the follicular fluid of a follicle in a recruited wave, prior to morphological selection of the dominant follicle, was more predictive of future dominance than follicular diameter or concentration of estradiol in the follicular fluid. Further details about these studies in vivo can be found in Fortune et al. (2001, 2004).

Fig. 5 Hypothesized sequence of events during selection of the dominant follicle in cattle. This model suggests that a critical event of “biochemical selection” is the induction by FSH of a protease for IGFBP-4/–5 in one follicle of a cohort and that biochemical selection quickly leads to “morphological selection” and further differentiation of the dominant follicle. Taken from Fortune, J.E., Rivera, G.M., Evans, A.C.O., and Turzillo, A.M. (2001). Differentiation of dominant vs. subordinate follicles in cattle. *Biology of Reproduction* 65, 648–654, with permission.

These results provide an example of how a biochemical change (increase in PAPP-A) can precede and lead to morphological (size) dominance. There is also extensive evidence for changes in components of the IGF system, including PAPP-A, during development of dominant follicles in a number of mammalian species besides cattle, including pigs, sheep, horses, and humans (see review by Spicer, 2004). There may well be other changes/mechanisms besides changes in the IGF system that serve to promote selection of follicles for dominance before size deviation by promoting the same end result of increased capacity for estradiol synthesis (Mihm and Evans, 2008). Different species may have somewhat different mechanisms and it would not be surprising if there were redundant mechanisms because selection of a species-specific number of dominant follicles is so important for reproductive success of females.

Development of Preovulatory Follicles

In species with multiple waves of follicular development, it is useful to distinguish morphological dominance from one aspect of functional dominance, the ability to suppress new follicular waves. Nonovulatory dominant follicles lose functional dominance before they lose morphological dominance. In nonovulatory waves in cattle, the growth of the dominant follicle plateaus for several days before a decrease in diameter (regression) is observed. Early in the plateau phase, the dominant follicle can resume growth if the corpus luteum is regressed with PGF2 α , but a day or two later it cannot and the dominant follicle of the new wave that has just emerged will ovulate in response to luteolysis (reviewed in Fortune et al., 1991).

In species with multiple waves of follicular development, the follicle that is dominant at the time of luteal regression transitions to a new phase of development; it continues to grow and to increase its capacity to produce estradiol. This is stimulated by the decrease in circulating progesterone during luteal regression, which causes an increase in basal levels of LH. In sheep and cattle the increase is manifested as an increase in LH pulse frequency once the negative feedback effects of luteal progesterone are removed. This change, coupled with the lower levels of circulating FSH, is sometimes described as a shift in the follicle from FSH-dependence to LH-dependence. Although the estradiol made by the dominant follicle decreases basal FSH, there is evidence that dominant follicles are still dependent on those normal basal levels and undergo regression if FSH is depressed further (reviewed in Fortune, 1994). However, the increase in basal LH during the latter part of the follicular phase seems critically important to convert the dominant follicle into a preovulatory follicle, capable of secreting quantities of estradiol sufficient to elicit the gonadotropin surge. Although the granulosa cells acquire LH receptors as the ovulatory follicle develops, it is not clear that LH directly increases the follicle's ability to make estradiol via effects on granulosa cell aromatization of androgen to estradiol (and some evidence against this). However, it may do so indirectly by increasing production of progestins by granulosa cells for conversion to thecal androgens. It seems possible that the major effect of the increased circulating LH is on the theca cells, to increase their production of androgen precursor for conversion to estradiol by granulosa cells in which aromatase has been induced and is maintained by FSH (Hampton et al., 2004).

Periovulatory Follicles

The preovulatory surge of LH and FSH is induced when the feedback of estradiol on the hypothalamus/pituitary changes from negative to positive, as circulating estradiol increases beyond a species-specific threshold. The gonadotropin surge converts preovulatory follicles into periovulatory follicles; a complex cascade of changes is triggered by the surge, causing profound morphological and functional changes in the follicles. The changes induced by the surge lead to meiotic maturation of the oocyte, cumulus expansion, and the structural and functional changes that produce rupture at the apex of the follicle. Androgen and estradiol secretion by the follicle cells decrease rapidly and progesterone levels increase, as the follicle enters the initial stages of luteinization. Detailed consideration of the events of the periovulatory phase of antral follicle development is beyond the scope of this article.

Summary

Mammalian follicles begin to form an antral cavity when they are 0.2–0.4 mm in diameter. Once they reach a particular, species-specific size, they either become atretic or are recruited by a small increase in circulating FSH to grow larger. From each recruited wave of follicles, a species-specific number is selected for dominance (i.e., further growth and potential ovulation), whereas the remaining, subordinate follicles gradually regress. Waves of follicular development occur once or more than once during estrous and menstrual cycles, depending on the species. Dominant follicles are characterized by a greater capacity to produce estradiol and by the appearance of LH receptors on their granulosa cells. There is evidence that changes in the IGF system within the follicle precede and facilitate the increase in estradiol production by dominant follicles. The increase in estradiol terminates the small rise in FSH that initiated the waves by negative feedback, thus depriving the subordinate follicles of the FSH they need to develop further. As dominant follicles develop towards ovulation, the increasing levels of estradiol in the circulation induce the gonadotropin surge that causes meiotic maturation of the oocyte and rupture of the follicle (ovulation).

Follicle Atresia

Elizabeth A McGee and Jessica Horne, University of Vermont Larner College of Medicine, Burlington, VT, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Atresia 1. Absence or closure of a natural passage of the body. 2. Absence or disappearance of an anatomical part (such as an ovarian follicle).

Bleb A vesicular outpocketing.

Caspase Any of several intracellular proteases that have a cysteine residue at their active site, that cleave substrate proteins at specific aspartic acid residues, and that are involved in the initiation and mediation of apoptosis.

Dictyate The dictyate or dictyotene is a prolonged resting phase in oogenesis. It occurs in the stage of meiotic prophase I in oogenesis. It starts late in fetal life and is terminated shortly before ovulation by the LH surge.

Graafian follicle The follicular stage after the first meiotic division but before ovulation containing a 2N haploid oocyte. It is characterized by a large follicular antrum that makes up most of the follicle.

Hypophysectomy The surgical removal of the pituitary gland.

Oogonia An immature female reproductive cell that gives rise to primary oocytes by mitosis.

Rete ovarii A transient network of cells in the developing ovary formed from the primary sex cords in females; homologous to the rete testis. It is a narrow hilus, at which nerves and vessels enter the ovary.

Introduction

Atresia in biology generally means the closing or failure to open of a tubular structure such as with vaginal atresia or esophageal atresia. However, follicle atresia has come to mean the failure of a follicle to develop to ovulate and release an egg. There is some disagreement on what stages of follicle loss are included when describing follicle atresia. Some scholars consider follicle atresia to have occurred only after follicles have grown to a certain size, but other scholars also include follicle or oocyte loss at any time after oogonia have migrated to the genital ridge as putative oocytes. In this article, we will discuss follicle loss over the span of follicle development.

There has been a great deal of research and advancement in the study of follicle loss over the preceding decades and much is known about the regulation of the growth and death of ovarian follicles in mammals, however little is known about why some follicles survive many years, even decades, while others are lost during development (McGee and Hsueh, 2000). A key advancement in understanding follicle atresia was the discovery that it is the result of the highly regulated process of apoptosis or programmed cell death. Apoptosis is a very important process in mammalian ovarian physiology. It is differentially regulated in different follicle stages and different ovarian cell types (Markstrom et al., 2002).

Apoptosis is a highly regulated process, important throughout development of virtually every system. It eliminates cells by enzymatic deconstruction and generally does not engage the inflammatory process. Apoptotic cells shrink, form blebs, and undergo patterned DNA fragmentation and membrane fragmentation into apoptotic bodies. Many of the events of apoptosis are measurable. Pro- and antiapoptotic genes are expressed and cell and follicle stage specific patterns and can be regulated by growth factors and cytokines and even small RNA. Apoptosis can be detected and quantified by numerous techniques such as those that measure DNA fragmentation, detect particular lipid patterns, gene expression analysis, and even morphological analysis (Elmore, 2007). These techniques and others have been used to characterize the role of apoptosis in ovarian function. The following sections will discuss what we know about apoptosis pathways and their regulation in ovarian tissues and follicles.

Pathways of Apoptosis

Intrinsic Pathway

There are at least two pathways that when activated lead to apoptotic death. They are often described as the intrinsic and extrinsic pathways in the classic canonical terminology (Fig. 1). The intrinsic pathway can be activated by cell stress events such as radiation, oxidative stress, or hormone withdrawal and may involve the activation of P53. The common feature is that small death molecules, either Bax or Bak, are activated resulting in the release of cytochrome *c* from the mitochondria. When cytochrome *c* is released into the cytoplasm it results in the activation of caspase 9 which then cleaves caspases 3, 6, 7 and initiating the caspase cascade.

Fig. 1 A basic schematic comparison of the extrinsic and intrinsic pathways of apoptosis. *TNF α* , tissue necrosis factor alpha; *BAX*, Bcl-2-associated X protein; *BAK*, Bcl-2 homologous antagonist killer.

Extrinsic Pathway

In the extrinsic pathway of apoptosis, cell surface receptors are activated by cytokines or factors such as Fas ligand or *TNF α* . In this pathway, the death receptors (Fas or *TNF α* R) are activated and then activate a multi-protein death inducing signal complex (DISC). The assembled DISC apparatus can activate caspase 8 or caspase 10, which can in turn activate caspases 3, 6, and 7 and initiate the caspase cascade similarly to the intrinsic pathway.

Caspase Cascade

Caspases are the enzymatic engine of apoptosis. These protein cleaving enzymes affect their cut at locations adjacent to aspartic acid residues. Caspases can cut a large variety of proteins that are essential to maintaining cellular function. Caspases cleave and activate the endonuclease that causes the fragmentation of DNA into the characteristic sizes as well as cleaving other proteins with additional downstream effects. The collective action of the mass cleavage of cellular and structural proteins defines the features of apoptosis and results in dissolution and ultimately phagocytosis of the cell.

The process of apoptosis can be regulated by factors that either promote (proapoptotic) or prevent (antiapoptotic) the activation of the pathways of apoptosis.

Bcl-2 is a molecule that acts to block the actions of the death initiating proteins (Bad, Bak, and Bok). Factors that up regulate Bcl-2 are generally survival factors. Factors that decrease Bcl-2 or increase the expression of death proteins increase apoptosis. Individual cell life or death is often based on the balance of pro- or anti-factors that either push the cell into the caspase cascade or block progression towards cascade activation. The extrinsic pathway can be regulated by proteins such as c-FLIP that bind or block the death domain in the receptor or associated adaptor proteins that can then prevent the formation of the DISC (Hussein, 2005).

Ovarian Formation and Folliculogenesis

Germ cells migrate from the yolk sac to the genital ridge as oogonia. They become organized into cords within the embryonic ovary, and the putative pregranulosa cells migrate into the cords around the oogonia, thus forming the primordial follicles. As the somatic granulosa cells separate an oogonia from others in the cord, it becomes an oocyte within a primordial follicle. Primordial follicles can remain relatively inert in mammals for many years (up to 5 decades in humans), though some will begin to grow almost immediately after formation. Germ cells that do not become invested with a ring of primordial granulosa cells undergo apoptosis.

The regulation of follicular growth is complex and stage specific. Follicles progress from primordial to primary, multilaminar preantral, early antral, antral, and ultimately a few survivors become a Graafian follicle. Graafian follicles may ovulate, releasing an egg and then transforming into a corpus luteum (Fig. 2). If pregnancy does not occur, the corpus luteum itself regresses into a corpus atretica. Less than 0.01% of human primordial follicles will ever ovulate. The fate of the vast majority of follicles is atresia.

The entire population of follicles is generally thought to be created early in mammalian life; in utero in humans and just after birth in rodents. The first wave of follicles begins to grow just after formation, though these early follicles do not make it to ovulation. Only after puberty does the pituitary secrete gonadotropins in the patterns necessary to support the growth of a dominant follicle and its ovulation (McGee and Hsueh, 2000).

Fig. 2 A schematic of the progression of follicle development. The *curved arrows* represent the loss of follicles to apoptosis at the various stages labeled with factors or miRNAs that promote atresia/apoptosis at that stage.

Atresia Across Early Folliculogenesis

Migration and Loss or Survival

Migration of germ cells from the yolk sac endoderm to the genital ridge is a critical event of gonad formation. Interaction of the germ cells with coelomic epithelium and the mesonephric tissue are required for formation of the ovary. However the germ cells that do not complete the journey to the gonadal ridge generally do not survive and are lost to apoptosis.

Though the process has not yet been clearly characterized in humans, there are genes expressed in both drosophila and mice that are involved in apoptosis of errant germ cells. *Scattershot* and *outsiders* both can cause apoptosis of germ cells that do not make it to the gonadal ridge. The regulation of the removal of ectopic germ cells is not yet fully understood. It is thought that germ cells that find a niche in which prosurvival pathway activation can occur may elude the usual fate of apoptosis and survive to become germ cell tumors.

After Arrival at the Gonad

Once the oogonia reach the genital ridge they must continue to proliferate but also avoid apoptosis. Oogonia that become invested with a layer of pregranulosa cells from the cords derived from the rete ovarii become primordial follicles, whereas oogonia that are not incorporated into follicles, ultimately undergo apoptosis (McGee et al., 1998). In mice and rats, the primordial follicle units begin assembly in the first day after birth. Most investigators think that the oogonia that do not enter meiosis and become oocytes in primordial follicles are lost to apoptosis. During this time there is an increased rate of apoptosis as shown in the DNA fragmentation patterns in Fig. 3.

Fig. 3 A ladder gel of DNA fragmentation patterns from whole ovary lysates from rats on day 1, 2, or 3 of life. There are prominent ladder bands in the lane for Day 1 but almost no DNA fragmentation is detected by Day 3. Modified from McGee, E. A., Hsu, S. Y., Kaipia, A. and Hsueh, A. J. W. (1998). Cell death and survival during ovarian follicle development. *Molecular and Cellular Endocrinology* **140**(1–2), 15–18 with permission.

Primordial Follicle Resting Pool

Once the oocytes are in primordial follicles, they arrest at the dictyate stage of meiosis one and are seemingly suspended in development. The regulation of the initiation of growth of the primordial follicle is quite complex and covered in another chapter. Follicles can be lost from the resting or nongrowing pool of follicles by death or damage but also by entering the growth phase. The difficulty in studying small follicles and lack of material available for investigation has limited progress in understanding which process is more responsible for follicle loss related to various biological and iatrogenic processes. It has been shown that chemotherapeutic agents can differentially affect oocytes versus granulosa cells in primordial follicles and some investigators have demonstrated follicle loss prior to entering the growing pool ([Morgan et al., 2012](#)).

Growth or Death; Apoptosis Over the Course of Follicle Maturation

Once follicles are activated and enter the growing pool, only a small fraction will continue to develop to ovulation. Though growing follicles are lost at all follicle stages there are some developmental points where apoptosis is more likely to occur.

In small follicles the establishment of oocyte/granulosa cell communication is important to further development. GDF-9 an oocyte derived growth factor in the TGF β family is important to developing a theca layer and in granulosa cell proliferation. Without GDF9, follicles are lost prior to the development of the full second layer of granulosa cells. Stem cell growth factor receptor, more commonly known as c-Kit, is also an important factor in early follicle cell–cell communication and is a survival factor for preantral follicles ([Huang et al., 1993](#)).

Prior to development of an antrum, follicles can grow in response to FSH, but they are not dependent upon it for survival. Survival of preantral follicles is dependent on the presence of cGMP, though the exact mechanisms controlling cGMP production and maintenance in small follicles have not yet been completely described.

There are other factors that have been identified as growth factors for preantral follicles such as KGF, GDF9, IGF1, and activin. However, TGF β can promote apoptosis of granulosa cells in preantral and small antral follicles. One mechanism by which TGF β promotes apoptosis is by increasing the expression of the inhibitory signaling molecule Smad7 ([McGee and Raj, 2015](#)). There is also a microRNA that can block Smad7 and acts to promote survival ([Worku et al., 2017](#)). With the development of in vitro folliculogenesis and other fertility preservation strategies there will likely be further definition of the regulators and regulatory pathways involved in both growth and survivorship of preantral follicles.

In small antral follicles, FSH is the primary factor that rescues follicles from atresia. Follicles at this developmental stage are dependent upon FSH for survival and further development. Withdrawal of FSH by hypophysectomy or pituitary suppression results in widespread apoptosis of all follicles beyond the antral stage in rodents. This can be prevented by adding back or treating with FSH. In culture, substances that elevate cAMP (the second messenger of the FSH receptor) in the cytoplasm can rescue antral stage granulosa cells from apoptosis. Thus the FSH stimulated production of cAMP and activation of the protein kinase A (PKA) pathway is necessary to prevent apoptosis of antral follicles.

Interestingly, there are far more factors that have been identified as survival factors for preovulatory follicles than at the earlier stages of folliculogenesis. Though both FSH and LH are primary survival factors for preovulatory follicles, there are many other paracrine and autocrine factors with a role in promoting survival such as GH, IGF1, EGF, FGF-2, IL1 β , and nitric oxide. These factors can augment the gonadotropin effect and can also reduce the threshold of gonadotropin needed to promote survival ([Table 1](#)).

Clinical Relevance of Follicle Atresia

Atresia of follicles during development permanently removes an egg from the pool. As such the process of atresia has a profound effect on the selection of mature germ cells that have the possibility to become embryos. Regulation of atresia can have an effect on fertility and over time, evolution of a species. The default pathway of a follicle seems to be apoptosis after the antral stage is reached and is regulated by phosphorylation state of the BCL-2 interacting proapoptotic proteins present in granulosa cells. Apoptosis is a differentiated energy dependent process. Under appropriate conditions a few follicles are rescued from atresia and continue on in development. FSH is the primary survival factor in antral follicles and is not readily available until after puberty. In the post pubertal ovary, FSH is the primary survival factor from the antral stage up to the preovulatory follicle. We know from animal studies and human IVF that increasing FSH levels can increase the number of follicles in a cohort that survive and grow to produce a mature egg.

The dynamics of follicle selection and dominance in humans remains an area of many unknowns. We know that there is variation in egg capacity for fertilization and competence for development as an embryo after fertilization. We also know that more maturing follicles containing healthy eggs are available in a penultimate cohort than the ovulatory quota for a species. However we do not fully know why one follicle achieves dominance and ovulates while the others are relegated to atresia. It could be that the process of cyclic production of a cohort of follicles competing to become one of the ovulatory complement could be key underlying feature regulating the reproductive process and assuring a fit oocyte becomes available for fertilization. We also do not know what role the egg plays in the earlier stages of folliculogenesis in assisting in the escape from atresia. However we do know that the follicle unit comprised of theca, extracellular matrix, granulosa, and oocyte is a complex structure with inter- and intracellular

Table 1 Survival and death factors by follicle stage

Introduction to Ovulation

Ovulation of an oocyte capable of being fertilized is a critical function of the female gonad, the ovary and is obligatory for reproductive success. Ovulation is a *unique biological process* that is so precisely regulated that in most mammals less than 1% of all oocytes present at birth are ever released from the surface of the ovary. Most ovarian follicles die by the process of atresia; granulosa cells undergo programmed cell death (apoptosis), oocytes degenerate, and theca cells become part of the ovarian stroma. Thus, the follicle that ovulates is the one that is in the right place at the right time. More specifically, the follicle that ovulates has acquired specific functions that allow it to respond to the ovulatory surge of luteinizing hormone, LH. A specific characteristic of preovulatory follicles is the induction of LH receptors in granulosa cells; LH receptors are not present in granulosa cells of small growing follicles. The LH responsive granulosa cells in preovulatory follicles control the molecular and cellular events that culminate in ovulation.

Although ovulation is often referred to as “rupture” of the ovulatory follicle, the process is not explosive. Rather, the release of the oocyte surrounded by cumulus cells is an extrusion process and occurs, in part, by degradation of the follicle wall (Adams et al., 2016).

Introduction to the Preovulatory Follicle

Successful ovulation in response to the LH surge involves multiple cell types (Richards et al., 2015; Adams et al., 2016). These include the theca cells, granulosa cells and cumulus cells within the preovulatory follicle itself. In essence, the follicle is a multilayered sphere, each layer being separated from the other by a specialized extracellular matrix. The theca cell layer is the outmost layer of cells in the preovulatory follicle and is composed of the theca externa and theca interna. The theca externa contains fibroblasts that generate extracellular collagen to provide a semirigid, supportive structure around the follicle. The theca externa is also endowed with an elaborate vascular network that supplies nutrients and oxygen to the follicle. The granulosa cell layer is separated from the theca layer by a thin collagen/laminin-rich basal lamina. This matrix provides an attachment surface for the outer-most layer of granulosa cells, the mural granulosa cells. The remaining granulosa cells form a syncytium in which they are interconnected by specialized gap-junctions, composed primarily of connexin 43 (GJA1). The cumulus cells, the inner layer of somatic cells, surround the oocyte, forming the cumulus cell–oocyte complex (COC). The cumulus cells are separated from the oocyte by the zona pellucida, a matrix of specific glycosylated zona proteins that serve to protect the oocyte and to provide structure and function during fertilization. The zona also allows for the attachment of cumulus cells and their connections with the oocyte via gap junctions, comprised exclusively of connexin 37 (GJA4), in the COCs that are critical for oocyte development.

Ovulation also depends on other cell types associated with the preovulatory follicle, including surrounding stromal and vascular tissues, immune cells, and the ovarian surface epithelium (OSE). These tissues undergo structural and functional changes during ovulation. For example, at the ovarian surface, the morphological events associated with ovulation involve the dissolution of collagen fibers in the theca layer and the consequent thinning of the surrounding stromal tissue. The vascular network in the theca cells of ovulating follicles becomes highly hyperemic and dilated, indicative of the inflammatory-like activities that are occurring in the somatic cells. The prostaglandins (PGs), cytokines, and chemokines that are being released alter vascular functions and recruit immune cells that are essential for ovulation and luteinization. Ultimately, the basal lamina of the OSE, that separates the apex of the follicle from the peritoneal cavity (human and other species) or bursa (mouse, rat), loosens and permits the release of the expanded COCs. The COCs are then picked up by the ciliated cells of the fimbria and transported to the oviduct where fertilization occurs. Successful release of the oocyte must occur before luteinization, otherwise the oocytes are trapped with the corpora lutea.

The Role of LH in Ovulation

The LH Receptor

It is now axiomatic that only preovulatory follicles are capable of ovulating in response to the ovulatory surge of pituitary LH. This has been experimentally established in most (all?) mammals studied by the evidence showing that granulosa cells in preovulatory follicles selectively express elevated levels of LH receptors that bind LH or exogenously administered hCG (Richards et al., 2002). Moreover, only granulosa cells and not cumulus cells express the LH receptor. Biochemically, the LH receptor belongs to the G-protein coupled receptor superfamily. When the ligand LH binds to the LH receptor it activates adenylyl cyclase leading to the production of cAMP and stimulation of cAMP-dependent protein kinase (protein kinase A). Protein kinase A in turn phosphorylates proteins that regulate the transcription of specific genes. These genes then lead to other events that impact the ovulation process (Fig. 1).

A major milestone in our understanding of the molecular events controlling ovulation came with the discovery that the LH surge via the cAMP-protein kinase A pathway induced the expression of specific epidermal growth factor (EGF)-like ligands (amphiregulin,

Fig. 1 The ovulatory LH surge initiates a cascade of cellular and molecular events that culminate in expansion of the cumulus oocyte complex (COC) and ovulation. COC expansion is induced by the EGF-like factor-EGF receptor (EGFR)-RAS-MAPK pathway that leads to the production of prostaglandins. Prostaglandins regulate the expression of genes involved in the formation and stabilization of the COC matrix. The EGF-like factor-EGFR pathway also leads to the activation of the transcription factors C/EBP α/β that impact ovulation and formation of the corpus luteum (luteinization). LH also induces the progesterone receptor (PGR) that impacts events leading to successful rupture of the preovulatory follicle and ovulation. Adapted from Richards JS, Pangas SA (2010). The ovary: Basic biology and clinical implications. *Journal of Clinical Investigation* 120, 963–972 PMID: 20364094; PMCID:PMC22846061 and Richards JS, Liu Z, Shimada M (2015). Ovulation. In: Plant TM, Zeleznik AJ (eds). *Knobil and Neill's physiology of reproduction*, 4th edn. Academic Press: Waltham, MA. pp. 997–1021.

AREG; epiregulin, EREG, and betacellulin, BTC) in granulosa cells (Conti et al., 2005). These EGF-like ligands bind and activate the EGF receptors present on granulosa cells and cumulus cells. Activation of EGF receptors leads to the activation of down-stream targets including the mitogen activated protein kinases (MAPK3/1) (also known as ERK1/2). Based on gene knock out studies in mice, this cascade is essential for ovulation. Mice null for the EGF receptor in granulosa cells exhibit impaired ovulation, cumulus cell–oocyte expansion, oocyte maturation, and luteinization. Conditional disruption of the mitogen activated protein kinases (MAPK3/1; ERK1/2) in mice blocks these same events (Richards and Pangas, 2010). Collectively, these observations document that the EGF-like factors and their receptors are key intracellular mediators of LH action and impact many critical events controlling ovulation. These include the production of prostaglandins, the induction of the progesterone receptor, and the expansion of the cumulus cell oocyte complex (COC).

A Central Role of ERK1/2 (MAPK3/1)

The expression of the *Lhcgr* gene is not altered in granulosa cells of *Mapk3/1* mutant mice indicating that the LH receptor is up-stream of these genes. Many genes that are expressed at high levels in granulosa cells of preovulatory follicles are normally down-regulated as a consequence of the LH surge. These genes include *Fshr*, *Cyp19a1*, *Foxo1*, *Ctgf*, *Ccnd2*, *Inhba* as well as *Lhcgr* itself (Richards and Pangas, 2010). However, in the *Mapk3/1* mutant mice these genes are not down-regulated. Thus, activation of the MAPK3/1 pathway by LH and the EGF-like factors is essential not only for turning on genes that regulate ovulation and luteinization but also for turning off genes that establish and maintain the preovulatory granulosa cell phenotype. It is impressive to observe that healthy preovulatory follicles remain present in the *Mapk3/1* mutant mice following administration of an ovulatory dose of LH whereas corpora lutea are fully formed in the wild type control mice similarly treated. Thus, activation of MAPK3/1 is critical for both ovulation and the terminal differentiation of granulosa cells to luteal cells. It is also important to note that disruption of *Mapk3/1* in the pituitary causes infertility in female (but not male) mice by blocking the LH. Thus, the MAPK3/1 pathways in the pituitary and ovary are both critical and tightly integrated to control ovulation.

C/EBP α and C/EBP β

Among the many transcription factors that are essential for ovulation are the CCAAT enhancer binding proteins alpha and beta (C/EBP α/β) (Richards et al., 2005). These are phosphorylated and activated by MAPK3/1. Conditional depletion of *Cebpb* and *Cebpa*

genes in granulosa and cumulus cells using *Cyp19-Cre* mice disrupts ovulation and luteinization and the mice are infertile. Gene profiling of granulosa cells obtained from the *Cebpa/b* mutant mice revealed a novel set of genes that are mostly down-stream of MAPK3/1 and appear to control the neovascularization of the ruptured, ovulated follicle. Major target genes are *Runx2*, specific transporters, the prolactin receptor, and the acute phase marker serum amyloid A.

The Role of Prostaglandins in Ovulation

Studies in the 1980–90s documented that an ovulating follicle exhibits physical characteristics of inflammation, including hyperemia and edema as well as biochemical features of inflammation including the production of prostaglandins (PGs) and the presence of immune cells. That ovulation was blocked by an inhibitor of prostaglandin biosynthesis, indomethacin supported the hypothesis that ovulation is an inflammatory-like response (Espey, 1980). Since then many studies have supported and expanded this insightful hypothesis (Richards et al., 2002).

From 1991 to 1993, two distinct forms and molecular weight variants (69 and 72 kDa) of the prostaglandin synthase (PGS), the rate-limiting step in prostaglandin biosynthesis, were identified in rat ovarian tissues (Richards, 2006; Richards et al., 2015). These observations provided the first evidence that there was not just one enzyme but two enzymes controlling prostaglandin biosynthesis. Furthermore, LH induced the 72 kDa form specifically in granulosa cells of ovulating follicles, whereas the 69 kDa form was constitutively expressed in theca cells and other tissues. Purification of the 72 kDa inducible form of PGS and amino-terminal sequence results documented that the inducible form was distinct from the constitutive form. Ultimately, the genes encoding each distinct protein were cloned and are now known as prostaglandin synthase1, PTGS1 (also known as cyclooxygenase 1; COX1) and PTGS2 (cyclooxygenase 2; COX2).

Prostaglandins and COC Expansion

Prostaglandins are essential for stimulating the expansion of the cumulus cell–oocyte complex (COC) and COC expansion is essential for ovulation (Richards and Pangas, 2010). Specifically, the cumulus cells within the COC of a preovulatory follicle are tightly packed together around the oocyte. In response to the LH surge, the cumulus cells make an extracellular hyaluronan-rich matrix, dissociate and migrate from the oocyte to fill the follicular antral cavity. Because neither the cumulus cells nor the oocyte express LH receptors, LH induction of this process occurs by an indirect mechanism. Specifically, LH induces the EGF-like factors in granulosa cells which then activate the EGF receptors in the cumulus cells. Activation of the cumulus EGF receptors leads to the induction of PTGS2 and production of prostaglandins, mainly PGE2. Prostaglandins made by cumulus cells then bind their G-protein coupled receptor (EP2) present in cumulus cells leading to activation of AC, cAMP, and protein kinase A and additional induction of EGF-like factors. Thus, cumulus cell-derived prostaglandins assume the role of LH. EGF-like factors alone or prostaglandins alone can induce COC expansion in the absence of LH. These observations established a unique intrafollicular regulatory loop (Richards et al., 2015).

Although the precise mechanisms by which COCs are released from the ovary remain to be determined, successful expansion of COCs by EGF-like factors and prostaglandins depends on their ability to induce factors that bind to and stabilize the hyaluronan polymers that form the backbone of the expanded matrix. Specifically, the LH surge rapidly induces expression of hyaluronan synthase 2 (*Has2*) that generates hyaluronan. The factors that stabilize hyaluronan include tumor necrosis factor alpha induced protein 6 (*Tnfaip6*), pentraxin 3 (*Ptx3*), and the proteoglycan versican (*Vcan*). TNFAIP6 delivers a serum factor IxI to the hyaluronan backbone. PTX3 binds exclusively to TNFAIP6. Versican binds hyaluronan and is the preferred substrate for the protease ADAMTS1. Collectively, these components form a scaffold on the matrix and each is essential for COC expansion. Targeted disruption of matrix-related genes *Ptgs2*, *Ep2*, *Has2*, *Adams1*, *Tnfaip6*, *Ptx3*, and *Ial* in mice (or in culture) impairs COC expansion; the mutant mice are infertile or subfertile (Richards et al., 2015). If the COC matrix is not made appropriately and lacks the hyaluronan backbone (made by HAS-2) or is not stabilized by the scaffolding of proteins that bind the hyaluronan polymers directly (IxI heavy chain and versican) or each other (IxI-TNAIP6-PTX3), COCs are not released and, as a consequence, the oocytes are trapped inside the non-ovulated, luteinized follicles.

Cumulus Cells Are Unique

Cumulus cells are distinct from granulosa cells in many ways (Richards et al., 2002). As indicated above, they are in close physical contact with the oocyte and thereby are exposed to high levels of oocyte-derived regulatory factors that control their function. The oocyte-derived factors, such as GDF9, BMP15 and FGF8, act singly or in combination to suppress cumulus cell expression of the LH receptor (*Lhcgr*) and steroidogenic genes and promote the expression of other genes in cumulus cells (Hernandez-Gonzalez et al., 2006). Cumulus cells also have a distinct fate. During COC expansion, they are embedded within the expanded extracellular matrix, produce many cytokines and inflammatory factors, and are released from the ovary along with the oocyte at the time of ovulation (Espey and Richards, 2006). Importantly, factors within the matrix also control cumulus cell functions. Thus, each COC is a highly specialized microenvironment with inflammatory-like responses that control the formation and stabilization of the matrix (Richards et al., 2015). Hence, during ovulation, the oocyte is the center of a pronounced inflammatory reaction and is essentially treated as a foreign body and kicked out of the nest. The expanded COC matrix is also sticky and this feature is essential for the

ovulated COCs to adhere to the surface of the ovary. The fimbria of the Fallopian tube that is lined with cilia then picks up the COCs for transport to the uterus for fertilization.

The Role of Progesterone in Ovulation

Studies in the 1970–90s revealed that the ovulation process was also dependent on the increased production of the steroid hormone progesterone that occurs rapidly following the LH surge (Espey and Lipner, 1994). The progesterone synthesis inhibitor epostane blocked ovulation; this effect was reversed by exogenous progesterone. LH also rapidly induces the expression of a nuclear receptor that bind progesterone, progesterone receptor (PGR) in granulosa cells (Park and Mayo, 1991). The induction of PGR preferentially impacts the process of follicle “rupture” and extrusion of the oocyte more than it impacts COC expansion. Activation of PGR facilitates the induction of specific genes encoding ADAMTS1 that is a novel protease, synaptosome associated factor 25 (SNAP25) that is involved in protein secretion, cGMP dependent protein kinase 2 (PRKG2) and endothelin 2 (END2) that regulate vascular endothelial cells. Genes that are induced at later times after the LH surge and closer to the time of actual release of the oocyte from the surface of the ovary include, cytokines and chemokines as well as other genes whose functions remain to be defined. The essential roles of progesterone and its nuclear receptor were unequivocally documented by targeted disruption of the progesterone receptor in mice. The progesterone receptor knockout (PRKO) mice fail to ovulate, contain corpora lutea with entrapped oocytes and are completely infertile (Lydon et al., 1995). Molecular analyses comparing control and mutant follicles have documented that progesterone regulates the expression of several genes that are distinct from those regulated by prostaglandins but are also critical for ovulation (Russell and Robker, 2007). Thus, the roles of progesterone and PGRs in the ovulation process are distinct from those of PGs (Richards et al., 2015).

The Role of Cytokines and Chemokines in Ovulation

In cumulus cells, AREG induction of *Ptgs2* and the production of prostaglandins represent key mediators of inflammation. AREG also leads to the induction of other genes (*Alcam*, *Il6*, *Cd34*, *Cd52*, *Pdcd1*) associated with inflammation (Hernandez-Gonzalez et al., 2006). In addition to IL6 and other cytokines (*Ccl2*, *Ccl4*, *Ccl5*) are expressed in cumulus cells raising the possibility that cytokines and their receptors play distinct roles in the functions and fate of COCs prior to and after ovulation. IL6 alone can stimulate COC expansion and induce genes required for this process by activating the MAPK3/1 pathway and JAK/STAT pathways. IL6 also enhances embryo development (Richards et al., 2015). However, *Il6* null mice are fertile indicating that other cytokines being released from COCs may act in a redundant manner during ovulation to facilitate COC expansion and release. Many cytokines and chemokines recruit immune cells to the ovulating follicles. Recent studies have also proposed that there is a pituitary–ovary–spleen axis associated with ovulation that promotes the trafficking of immune cells to the ovulating follicle. That immune cells are recruited to ovulating follicles is highly relevant because recent studies also show that macrophages and dendritic cells are essential for ovulation, luteinization and vascularization of newly formed corpora lutea (Care et al., 2013; Cohen-Fredarow et al., 2014).

The Role of Immune-Related Factors

Components of the innate immune system are an evolutionarily conserved receptor recognition system that includes the pattern recognition receptors (*Cq1a*, *Cd14*, *Trl4*, *Thr2*). In immune cells these receptors are used to discriminate self from non-self and bind such factors as bacterial lipopolysaccharide, LPS/Pam3Cys. These receptors are also expressed in nonimmune cells including cumulus cells. In cumulus cells they are functional and bind LPS as well as fragments of hyaluronan (Richards et al., 2015). Specifically, LPS itself induces marked induction of *Il6* and *Ptgs2* in cumulus cells. Furthermore, fragments of hyaluronan that are generated by hyaluronidase that is released from cumulus cells or sperm also bind to these receptors and increase *Il6* and *Ptgs2*. Thus, cumulus cells have the potential to monitor their environment within the follicle and the oviduct.

The cGMP Pathway in Cumulus Cells

The resumption of meiosis is initiated rapidly by the LH surge and involves an intrafollicular paracrine network that controls production of cyclic GMP (Zhang et al., 2010). This network is comprised of the natriuretic peptide precursor C (NPPC) that is produced and secreted by granulosa cells. The NPPC ligand binds the natriuretic peptide receptor 2/guanylyl cyclase B (NPR2) that is present primarily in cumulus cells. Cyclic cGMP that is produced by activation of NPR2 in cumulus cells is then transferred to oocytes through gap junctions. Elevated levels of cGMP block PDE3A activity leading to elevated intra-oocyte levels of cAMP that block meiosis. The LH surge not only disrupts gap junctions and prevents cGMP from entering the oocytes but also reduces the expression of *Nppc* and *Npr2*. Activation of the EGF-MAPK pathway also disrupts this pathway leading to decreased cGMP in cumulus cells and the oocyte. Reduced levels of cGMP in oocytes leads to increased activity of PDE3A and lower levels of cAMP. Decreased levels of cAMP in oocytes permit the resumption of meiosis of ovulatory follicles.

In granulosa cells, another pathway can generate cGMP (Richards et al., 2015). This pathway is comprised of nitric oxide synthase 3 (NOS-3) that is induced by the LH surge and generates nitric oxides that activate soluble guanylyl cyclases and produce cGMP. cGMP-dependent protein kinase II (cGKII or PRKG2) is also induced by LH in a progesterone receptor (PGR)-dependent manner. Thus, PRKG2 may play a critical role in granulosa cells of ovulatory follicles by mediating the effects of cGMP, however, the precise functions of PRKG2 in ovulatory granulosa cells remain to be resolved.

The Role of Proteases in Ovulation

Ovulation involves and requires the breakdown of the basal lamina separating mural granulosa cells from theca cells as well as the dissolution of the basement membrane underlying the ovarian surface epithelium (Curry and Osteen, 2003). This “thinning” of the ovulatory follicle wall and the surface epithelium ultimately permits the extrusion of the COCs through the ovulation pore. This latter event appears to depend, in part, on EDN2 and smooth muscle contractions within the theca layer. The former events appear to involve various proteases and tissue protease inhibitors, the list of which is long and the functions of which are complex (Curry and Osteen, 2003). Despite much research, data from knockout mice lacking various proteases have shed little insight into which ones might be the key players close to or at the time ovulation. However, protease inhibitors can block ovulation as shown recently in primates (Peluffo et al., 2011). An outstanding and comprehensive reviews have covered this topic recently therefore, only one protease will be discussed herein (Curry and Osteen, 2003; Rosewell et al., 2015).

One novel protease called A disintegrin and metalloproteinase with thrombospondin-like repeats 1, ADAMTS1 is rapidly and markedly induced in granulosa cells of preovulatory follicles by the LH surge and in a progesterone-PGR-dependent manner. Not only does the temporal expression of ADAMTS1 (Richards et al., 2002) and its control by PGR (Robker et al., 2000; Russell and Robker, 2007) suggest its key role in ovulation, but also the functional activities of ADAMTS1 indicate that it is a key protease related to ovulation. Mice null for *Adams1*, as well as mice in which *Adams1* has been conditionally disrupted in granulosa cells, are sub-fertile. The proteoglycan versican is one of the preferred substrates for ADAMTS1 and is a key component of the extracellular matrix in expanded COCs and in the follicle wall. In the absence of ADAMTS1 both the invasion of the theca cell layer into the granulosa cell layer as well as the structure of the COC matrix are abnormal. How these defects ultimately cause subfertility and reduce release of COCs remains to be more clearly defined. ADAMTS4 and ADAMTS5 are also expressed and regulated in the mouse ovary (Richards et al., 2005) whereas ADAMTS1 and ADAMTS9 are regulated in human granulosa cells during ovulation (Wissing et al., 2014).

Translational-Clinical Implications

Polycystic Ovarian Syndrome at the Ovarian Level

Polycystic ovarian syndrome (PCOS) is the most common endocrine defect and cause of anovulatory infertility in women in their reproductive years. PCOS afflicts more than 5%–10% of women in the United States, costs more than \$4 million/year to manage and is becoming increasingly prevalent. A PubMed search of “ovulation” lists scores of papers that are predominantly related to current clinical studies describing ways to improve treatment of infertile women, especially those with anovulatory PCOS. The number of basic research papers on ovulation pales in comparison. Although some molecular aspects of theca cell androgen production have been determined in PCOS, our understanding of the molecular consequences of PCOS in granulosa cells and cumulus cells is less well defined.

Although elevated androgens (hyperandrogenemia) are one defining characteristic of PCOS, PCOS is also frequently associated with metabolic defects related to insulin resistance and a proinflammatory state that may contribute to insulin resistance. Thus, understanding the consequences of endocrine, cytokine and metabolic defects at the ovarian level are critical for improving ovulation, IVF procedures and oocyte quality in PCOS patients (Rosenfield and Ehrmann, 2016). PCOS is often, but not always, associated with obesity suggesting that cytokines or other factors coming from adipose tissue likely impact the hypothalamic-pituitary-ovarian axis. Two major cytokines derived from adipose tissue are leptin and adiponectin. Whereas leptin regulates appetite, adiponectin has been shown to alter steroidogenesis, genes involved in ovulation and those involved in apoptosis. That adiponectin enhances oocyte and embryo development in mice indicates that this may be a “good” cytokine. Furthermore, expression of adiponectin receptors is correlated positively with oocyte maturation in samples obtained from IVF patients. That levels of adiponectin are reduced in PCOS patients may indicate that it plays some role in optimal ovulation and oocyte quality.

In addition, there is a functional link between elevated androgens in PCOS patients and proinflammatory conditions at the systemic level. Cytokines such as CRP and TNF alpha released from adipocytes can cause proinflammatory reactions in cells. Moreover, inflammatory conditions within the ovarian stroma and granulosa cells of ovulatory follicles of PCOS patients undergoing IVF release elevated levels of cytokines and chemokines including IL6, IL7, CCL20 that recruit immune cells (Adams et al., 2016; Al-Alem et al., 2015). These observations document that there is an enhanced local, intraovarian inflammatory response associated with a PCOS patients, many of whom are obese.

Ovaries in women with anovulatory PCOS contain numerous small antral follicles that are characterized by high levels of androgens. However, these follicles also produce estradiol. Successful ovulation can be achieved frequently in PCOS patients by

decreasing estradiol or its actions and by judiciously increasing endogenous or exogenous FSH. These results indicate that anovulation is related not only to ovarian problems but also to hypothalamus–pituitary events. Ovarian hyperstimulation syndrome (OHSS) in which the ovary produces excessive amounts of estradiol and progesterone and ovarian blood vessels become highly leaky, is frequently associated with hormonal stimulation of IVF patients and complicates IVF outcomes. Therefore it is important to understand what factors contribute to PCOS and to OHSS, including what functions are altered in PCOS ovaries, including the ovarian vasculature.

Restoring Fertility With IVF, ICSI, and IVM

In vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) are the most frequent methods used for treating infertile couples. However, the effectiveness of IVF/ICSI procedures is compromised by the transfer of multiple embryos and multiple births. Now that we know many of the genes regulating COC expansion, these genes might be used as markers to identify healthy versus compromised oocytes during IVF. In vitro maturation (IVM) of oocytes provides promise as an alternative to IVF but oocyte quality remains an issue and better techniques need to be developed in the years ahead.

Summary

Ovulation is a complex process essential for the reproductive success of every species. Although we have learned a great deal about how LH initiates this process in mice and other mammals, there are still many blank spaces on the canvas and in the script. We know some of the transcription factors that are essential for ovulation but the regulatory networks that they control remain incompletely defined.

World population continues to soar and therefore, the need to regulate population growth remains critical in many areas of the globe. Conversely, rescuing fertility has a major impact on allowing infertile couples to have the children they desire. Therefore, understanding what regulates ovulation and oocyte quality are of prime importance for the development of new contraceptive approaches as well as for designing improved procedures for in vitro fertilization (IVF) of an oocyte and in vitro maturation (IVM) of follicles and oocytes. Although the transfer of some of our current knowledge to clinical issues is occurring, much still remains to be applied to IVF and especially IVM where conditions are less than optimal.

Corpus Luteum

Jon D Hennebold, Oregon Health & Science University, Beaverton, OR, United States

© 2018 Elsevier Inc. All rights reserved.

Glossary

Angiogenesis The formation of new blood vessels.

Luteinization The differentiation of follicular granulosa and theca cells into the cells that comprise the corpus luteum.

Luteinizing hormone A protein hormone secreted by the anterior pituitary that is responsible for initiating events necessary for ovulation and initiating corpus luteum development.

Luteolysis Loss of luteal progesterone producing potential and luteal cell numbers at the end of a reproductive cycle.

Maternal recognition of pregnancy Substances generated by the conceptus that signal the corpus luteum of the mother to maintain a level of progesterone synthesis that will support pregnancy.

Progesterone A steroid hormone produced by the corpus luteum that is necessary for preparing the uterus for embryo implantation and subsequently sustaining pregnancy.

Prostaglandins Lipid-derived molecules that are key mediators of luteal development (prostaglandin E₂; PGE₂) or luteolysis (prostaglandin F_{2α}; PGF_{2α}).

Introduction

The corpus luteum is remarkable in that it is critically important for reproduction in numerous species (mammals and some reptiles), but exists only as a transient structure that arises from the ovarian follicle after ovulation. Marcello Malpighi first coined the term corpus luteum (yellow body) in 1681. Regnier de Graaf (1641–73) was the first to describe and provide detailed illustrations of the corpus luteum present in the ovaries of pregnant rabbits, where it was noted that they possessed “globular bodies.” The essential role of the corpus luteum was not defined until 1901, when Ludwig Frankel demonstrated that rabbits could not maintain a pregnancy when all of the corpora lutea were removed. It was subsequently discovered in 1929 that extracts obtained from corpora lutea were able to replace the function of the ovaries once removed. Around this same time, several groups purified and defined this luteal derived steroid hormone and named it progesterone by joining the terms “progestin” and “luteo-sterone.” In the intervening decades, studies focused primarily on understanding the cellular processes that allow for the development of the corpus luteum following ovulation, its ability to produce large quantities of the steroid hormone progesterone, its regression in non-fecund cycles, as well as luteal regulation of pregnancy.

Since the corpus luteum forms from the antecedent ovulatory follicle, the number of corpora lutea are proportional to the number of ovulatory follicles that form and ovulate through each reproductive cycle (Fig. 1). Thus, in polyovulatory species, numerous corpora lutea are generated per cycle; whereas most ovine, bovine, and primate species develop a single follicle that yields one corpus luteum per reproductive cycle. Species have also evolved several different mechanisms that control the lifespan of the corpus luteum in the nonfertile cycle as well and how pregnancy affects luteal survival. Mammals can be divided into three major categories based on how long the corpus luteum functions after ovulation in the non-fecund ovarian cycle and how luteal lifespan is affected by pregnancy onset and gestation, including the following: (1) ultrashort-lived corpora lutea, (2) short-lived corpora lutea, and (3) long-lived corpora lutea.

Species that have ultrashort-lived corpora lutea do not form a functional corpus luteum (e.g., rodents) or any corpus luteum during the ovarian cycle unless ovulation is induced following copulation (reflex ovulators, e.g., rabbit) and/or pseudopregnancy or pregnancy (e.g., rat, mouse). In rodents, the ruptured follicle takes on certain structural and cellular characteristics of a corpus luteum, but does not secrete sufficient progesterone to allow for implantation. A requirement for the development of significant progesterone producing potential by the murine corpus luteum includes either mating that does not result in pregnancy (pseudopregnancy) or fertilization and pregnancy. Pseudopregnancy results in the development of functional corpora lutea that secrete progesterone for 12–14 days, whereas fertilization and implantation leads to continued progesterone secretion by the corpus luteum throughout gestation that is critical for maintaining pregnancy (~21 days).

Species that possess short-lived corpora lutea include many of the ungulates, such as domesticated farm animals (e.g., sheep and cattle), and primate species (e.g., monkeys, great apes, and humans). The short-lived corpus luteum develops and functions for a finite interval during the ovarian cycle in the absence of pregnancy (typically between 2 and 3 weeks), but its function is extended markedly if pregnancy ensues. This period of luteal progesterone synthesis allows for the timely movement of the early embryo through the oviduct and preparation of the uterus for implantation. If implantation and the establishment of pregnancy occur, progesterone production by the corpus luteum continues until the placenta assumes this activity (referred to as the luteal-placental shift). In primates, the luteal-placental transition takes place between 3 and 7 weeks of gestation. In domesticated

Fig. 1 The ovarian cycle and the formation of the corpus luteum. The luteal phase of the cycle encompasses the period of corpus luteum formation and its subsequent regression. The corpus luteum forms at the end of the ovarian cycle from the remnants of the ruptured ovulatory follicle. This cartoon depicts the ovarian cycle in a monovulatory species that results in the growth and development of a single follicle that ruptures and transforms into a single corpus luteum.

animal species, progesterone synthesis by the corpus luteum is sustained by pregnancy for several months, or even until the end of pregnancy, as occurs in the pig.

The absence of pregnancy leads to rapid luteolysis in species that have short-lived corpora lutea. However, there are important distinctions between primates and ungulates in terms of the processes that determine the length of the luteal phase as well as how maternal recognition of pregnancy is mediated. In the ungulate corpus luteum, antral follicle growth occurs during the luteal phase, which results in a very short (2–3 days) and well-defined interval between luteolysis and the development of the next ovulatory follicle. In most primates, however, small antral follicles do not develop until after luteolysis, resulting in a relatively long follicular phase (~1–2 weeks). Another distinguishing feature between ungulates and primates is that luteolysis in the former is dependent on a uterine-derived luteolytic signal that orchestrates corpus luteum regression; whereas in primates, hysterectomy does not alter the functional lifespan of the corpus luteum, indicating the absence of a uterine luteolytic signal. Lastly, while early pregnancy in ungulates and some New World monkeys prevents the synthesis of a uterine luteolytic signal, an embryonic hormone (chorionic gonadotropin) is produced by the conceptuses of Old World monkeys, apes, and women that sustains corpus luteum progesterone synthesis.

In some species that have estrous cycles of very long duration (i.e., every 6–12 months), the lifespan of a fully functioning corpus luteum does not differ between fertile or nonfertile cycles. Such species, including carnivores (e.g., dogs, wolves, foxes, cats, ferrets, skunks) and other animals such as the roe deer, armadillo and marsupials, possess corpora lutea that survive for as long as 6 months. In dogs for example, the length of the luteal phase in nonpregnant and pregnant animals is ~65 days, with rapid luteolysis occurring after delivery in pregnant animals. In the absence of pregnancy, luteal regression in these species generally encompasses a relatively prolonged period of time (i.e., weeks).

Corpus Luteum Development

After ovulation, the adjacent vasculature and the cellular remnants of the ruptured follicle undergo structural and cellular remodeling that ultimately results in the formation of the functional corpus luteum. The key events necessary for this transformation (e.g., luteinization) are coordinated by a midcycle surge of the pituitary-derived luteinizing hormone (LH). LH acts by directly binding to and signaling through LH receptors present on granulosa and theca cells. Alternatively, LH induces the synthesis of paracrine acting factors, such as progesterone or the fatty acid metabolite prostaglandin E₂ (PGE₂), both of which have been shown to promote luteal development and survival. Luteinization is a remarkable event involving initial rounds of cell proliferation, cell differentiation, and tissue remodeling that are unparalleled in terms of normal physiological processes. Luteal cell differentiation primarily refers to the transformation from predominantly estradiol synthesis via the steroidogenic activities present in both follicular granulosa and theca cells to progesterone production by the cells that comprise the corpus luteum.

Based on differences in size, morphology and cellular markers, the general belief is that the corpus luteum is comprised of at least two types of luteal cells, large luteal cells and small luteal cells. This distinction is somewhat species dependent in that rodents, for example, possess luteal cells that are relatively homogenous in terms of their size and distribution throughout the corpus luteum. In

contrast, the primate and ungulate corpus luteum possesses distinct small and large luteal cell populations. In ruminants, the larger luteal cells are endowed with organelles associated with a higher rate of cholesterol uptake and steroid/protein synthesis, which includes greater levels of smooth and rough endoplasmic reticulum, mitochondria, Golgi bodies, and secretory granules relative to small luteal cells. The most widely held view is that large luteal cells are derived from the granulosa cells of the follicle, whereas the theca cells of the luteinizing follicle give rise to the small luteal cell population. This hypothesis is supported by several lines of evidence, including that isolated granulosa and theca cells can be induced to undergo differentiation *in vitro* and develop many of the characteristics of large and small luteal cells, respectively. Moreover, monoclonal antibodies that uniquely recognize granulosa and theca cell surface antigens revealed that small luteal cells bound theca-specific antibodies, whereas large luteal cells bound either granulosa- or theca-specific antibodies. In primates, there is a spatial organization of small luteal cells and large luteal cells that mirrors the orientation of theca and granulosa cells in the follicle, wherein the inner layer of large luteal cells is surrounded by an infolded layer of small luteal cells (Fig. 2). Furthermore, removal of granulosa cells from the preovulatory follicle leads to reductions in luteal mass and serum progesterone levels in both domesticated animal species and primates. These studies establish granulosa-derived luteal cells as being a key contributor to the progesterone-secreting cells in the corpus luteum.

The overall steroidogenic potential increases as the corpus luteum develops, especially through the early-to-mid luteal phase in species with a short-lived corpus luteum. Increases in luteal cell number/size, along with vascular formation, are tightly coupled to overall corpus luteum function after ovulation as these events occur in parallel with the rise in circulating progesterone levels. Angiogenesis in the corpus luteum is unique from the standpoint of its rapidity and that it occurs as part of a recurring physiological event. Even in comparison to what is observed in tumors or the placenta, the level of luteal vessel and lymphatic development is remarkable. The initial cellular proliferation that is observed in the developing corpus luteum can be attributed mostly to microvascular endothelial cell expansion. Prior to the midcycle LH surge, the vasculature of the preovulatory follicle is restricted to a capillary network that does not extend beyond the theca layer (Fig. 1). After the LH surge, cellular and extracellular matrix remodeling results in the breakdown of the basement membrane that separates the theca cell layer from the granulosa cell layer, which also allows for the growth and invasion of new capillary beds and lymphatics into the forming corpus luteum. After the network of luteal vessels is formed, the number of endothelial cells is estimated to equal the number of luteal cells. This is particularly true in the primate corpus luteum, wherein there is a microvessel in direct contact with every luteal cell. It is thought that this close contact between steroidogenic luteal cells and the vasculature allows for rapid transfer of progesterone into the circulation for its distribution to responsive tissues.

The induction of endothelial cell proliferation and vessel growth is controlled by angiogenic factors that are secreted primarily by luteal cells. The pro-angiogenic substances studied to date in the greatest detail include the proteins that comprise the vascular endothelial growth factors (VEGFs). There are several different VEGF family members, but the various isoforms that constitute the VEGFA subgroup have received the most attention with regard to promoting luteal angiogenesis. VEGFA is produced by luteal cells and acts in a paracrine manner through specific cell surface VEGFA receptors that are present on microvascular endothelial cells. Whereas VEGFA production is strongly induced by hypoxia in many tissues or cells, evidence suggests that its production in the developing corpus luteum may also be directly regulated by transcriptional or post-transcriptional mechanisms that are induced by the midcycle LH surge.

Other factors acting locally often promote or counter-act the effects of the VEGFs, thereby controlling the overall density of the vasculature in the corpus luteum by directing vessel growth, stability, and regression. Thus, the level of angiogenesis that occurs

Fig. 2 Distinct small and large luteal cell populations in the primate corpus luteum. Histological hematoxylin and eosin stained sections of corpora lutea isolated from rhesus macaques 2–3 days after ovulation (early luteal phase; period of corpus luteum development), 4–5 days after ovulation (mid luteal phase; period of peak corpus luteum progesterone synthesis), or at the time of menses (late luteal phase; 2–3 days after luteal progesterone production ceases, time of menses). In contrast to rodent species, the corpus luteum from primates possesses distinct small and large populations of luteal cells. Insets are a higher magnification (scale bar = 25 μ m) of the region outlined by the black box present in each larger panel (scale bar = 100 μ m). The lines in the insets highlight the boundaries between regions containing primarily small (S) and large (L) cells.

during luteal development is tightly controlled by balancing the production of pro- and anti-angiogenic factors. As an example, the proteins angiopoietin-1 and -2 (ANGPTs) are essential for balancing vessel growth, stabilization, and regression. ANGPT1 recruits pericytes that surround and stabilize small vessels, whereas ANGPT2 promotes endothelial cell proliferation and capillary tube formation in the presence of VEGFs. A local ratio favoring ANGPT1 over ANGPT2 promotes capillary growth and maturation. When the levels of ANGPT2 exceed VEGF or ANGPT1, blood vessels are destabilized and capillary regression ensues. While the VEGF/ANGPT systems have received the most attention with regard to controlling angiogenesis in the corpus luteum, advances in genomic and molecular techniques revealed numerous other factors exist that also play an important role in this process.

Corpus Luteum Function in the Absence of Pregnancy

Producing sufficient quantities of progesterone to prepare the uterus for implantation and sustain early pregnancy is arguably the most important function of the corpus luteum. In women, it is estimated that at mid luteal phase, when steroid synthesis is at its peak, the corpus luteum produces 40 mg of progesterone every day, making it one of the most highly steroidogenic structures on a per weight basis. In contrast to nonprimate species, the primate corpus luteum also synthesizes significant amounts of estrogens. In primate species, pituitary-derived LH is critical for luteal function since blocking its secretion at mid luteal phase through the administration of gonadotropin releasing hormone (GnRH) antagonist stops progesterone synthesis and causes premature regression of the developed corpus luteum. By mid luteal phase, pulses of LH are actually entrained to corpus luteum progesterone secretion. In ruminants, the majority of circulating progesterone is derived from the large luteal cells that are thought to be independent of LH action. GnRH antagonist treatment of cows and sheep only modestly reduce circulating progesterone levels in a stage-specific manner. Large luteal cells of ungulates appear, therefore, to undergo a differentiation process that results in constitutive, LH-independent production of progesterone. In rodents, progesterone production by corpora lutea that develop following pseudopregnancy or pregnancy is not dependent on LH. Instead, prolactin production by the anterior pituitary or prolactin-like hormones from the uterine decidua and placenta are the essential luteotropins.

To accommodate such a high rate of steroid production, a significant supply of the steroid precursor cholesterol is required by luteal cells (Fig. 3). Data from studies utilizing inhibitors of *de novo* cholesterol synthesis revealed that the corpus luteum possesses only a very limited capacity to synthesize its own cholesterol. Instead, the corpus luteum is reliant on the uptake of circulating cholesterol from either high-density lipoprotein (HDL) or low-density lipoprotein (LDL) particles. Primate species preferentially utilize LDL, whereas in rodents HDL is the predominant source of cholesterol for steroid synthesis. Ruminants utilize either HDL or LDL as the source of cholesterol for steroid synthesis. Following cholesterol uptake from HDL or LDL, cholesterol can be stored in lipid droplets as cholesterol esters. Free cholesterol is then liberated by the actions of one or more lipase enzyme(s) and can then be transported to the mitochondria for entry into the progesterone synthesis pathway. Thus, another mechanism whereby luteal cells can acutely increase the availability of substrate for steroidogenesis is by hydrolysis of intracellular stores of cholesterol esters in lipid droplets.

The expression of key enzymes responsible for progesterone production, including CYP11A1 (side chain cleavage enzyme, converts cholesterol to pregnenolone) and HSD3B (3 β -hydroxysteroid dehydrogenase, converts pregnenolone to progesterone), increase in the follicle shortly after ovulation and through the initial stages of corpus luteum development (Fig. 3). In parallel, reduced expression of enzymes involved in androgen (e.g., CYP17A1) and estradiol (e.g., aromatase or CYP19A1) synthesis occurs, being more prevalent in species that do not secrete significant amounts of estradiol (i.e., ruminants). While elevated steroidogenic enzyme expression is important for luteal function, the key rate-limiting step in luteal progesterone production appears to be movement of cholesterol from the outer to the inner mitochondrial membrane, where the first step in steroid synthesis occurs. The protein responsible for mitochondrial cholesterol transport is termed steroidogenic acute regulatory protein (STAR), which has a high level of activity as each STAR molecule shuttles hundreds of molecules of cholesterol before undergoing a cleavage/inactivation event. In rodents, prolactin maintains steroidogenesis by upregulating enzymes involved in progesterone and estradiol synthesis, including STAR, as well as by inhibiting the expression of a gene (AKR1C3) that encodes an enzyme responsible for degrading progesterone. In ruminants, the differential control of STAR expression in large and small luteal cell types matches their ability to produce progesterone. Large luteal cells of ruminants constitutively express high levels of STAR in an LH-independent manner and are the source for the majority of the progesterone (~80%) that comes from the corpus luteum, whereas STAR expression and the limited amount of progesterone produced in small luteal cells is LH dependent. The primate corpus luteum, in contrast, is clearly dependent upon acute LH action since numerous studies demonstrated that blocking LH secretion from the pituitary at any point of the luteal phase inhibits the expression of key steroidogenic enzymes (e.g., STAR, HSD3B) and progesterone production.

Corpus Luteum Luteolysis

The key regulatory mechanisms that determine when and how the corpus luteum ceases to produce progesterone and undergo structural regression in non-fertile cycles is highly species dependent. A common underlying initiator of luteolysis in several species is prostaglandin PGF $_{2\alpha}$. PGF $_{2\alpha}$ is produced by the uterine endometrium of numerous species (e.g., sheep, cow, horse, pig, rodent, and rabbit) and is then transported through the circulation to the corpus luteum to initiate events that ultimately result in luteolysis. In mice, both luteolysis and parturition are intertwined and dependent on the action of PGF $_{2\alpha}$ since it is required to halt

Fig. 3 Luteal cell cholesterol uptake and utilization. Steroidogenic luteal cells obtain cholesterol from circulating sources, including HDL and/or LDL particles or from internal stores found within lipid droplets, which collectively provides the necessary substrate for progesterone synthesis. Cholesterol is transported into the mitochondria, where it is converted to pregnenolone. Pregnenolone leaves the mitochondria and is subsequently converted to progesterone in the endoplasmic reticulum, where it moves out of the cell and into the extensive vasculature that exists throughout the corpus luteum. Figure generated using ScienceSlides from VisiScience.

progesterone synthesis that in turn allows for the initiation of labor. $\text{PGF2}\alpha$ is well documented as the key luteolytic agent in domesticated animal species where it is produced by the uterine endometrium in non-fecund cycles. Hysterectomy in these species results in an extension of luteal lifespan by removing the source of $\text{PGF2}\alpha$ production. In primate species, however, regression is independent of a uterine-derived luteolytic factor as illustrated by the fact that luteal lifespan is not changed by hysterectomy. The finding that a uterine derived signal is not responsible for luteal regression suggests that an internal “self-destruct” mechanism is responsible for primate luteolysis at the end of the non-fecund menstrual cycle. One mechanism that has emerged as a regulator of luteal function in primates is the loss of sensitivity to the luteotropic hormone LH. It is well established that in the early luteal phase, LH pulses from the pituitary are frequent and luteal cells exhibit the greatest degree of LH sensitivity in terms of its ability to stimulate progesterone production. By mid-late to late luteal phase, LH pulse frequency declines and luteal cells are less responsive to LH due to the desensitization of the LH receptor. Loss of sensitivity to LH is an early indicator of functional regression in the primate corpus luteum and appears to be critical for its demise, since sustaining LH levels either by promoting endogenous LH pulses or administering exogenous LH does not prolong primate luteal lifespan. It is presently unclear if the loss of LH sensitivity in the primate corpus luteum is the primary initiator of luteolysis or if it is secondary to other luteolytic processes. With regard to the latter, intraluteal $\text{PGF2}\alpha$ synthesis and action has been proposed to serve as a primate luteolysin because the administration of exogenous $\text{PGF2}\alpha$ will directly induce luteolysis. Recent characterization of the cellular and molecular processes known to control prostaglandin synthesis, metabolism, and signaling suggest that changes in the balance from luteotropic prostaglandins (e.g., PGE2) to luteolytic prostaglandins (e.g., $\text{PGF2}\alpha$) may serve as intraluteal determinants of primate luteal regression. Another proposed pro-luteolytic substance is estradiol, which is based on the ability of the primate corpus luteum to produce and respond to estradiol through the estrogen receptor β ($\text{ER}\beta$, or ESR2). As progesterone production becomes entrained to pituitary-derived LH pulses just prior to the onset of functional regression, there are intervals where estradiol production continues that could promote luteal

demise during the nadir of luteal progesterone secretion. However, such a role for estradiol in serving as a key primate luteolysin has yet to be established. A more detailed overview of luteal regression, primarily as related to the well-characterized luteolytic mechanisms that occur in non-primate species, is provided in the next article.

Extended Corpus Luteum Function in Pregnancy

As is the case for luteolysis, the processes that are responsible for ensuring luteal survival and progesterone production through pregnancy are highly species dependent, contingent on whether they possess ultra-short, short, or long-lived corpora lutea. In rodents, continued luteal structure/function during pregnancy is dependent on a combination of prolactin and prolactin-related (e.g., placental lactogens) factors derived from maternal (pituitary, uterine) and fetal (trophoblast) sources that bind to the prolactin receptor expressed by luteal cells. Twice-daily pulses of prolactin production by the pituitary gland, induced by mating and continue through the first 8–9 days of pregnancy, serve to sustain rodent corpus luteum function. By approximately day 10–11 of pregnancy, placental lactogens assume the role as the predominant luteotropic hormone. In ruminants, the anti-luteolytic substance is interferon-tau (IFN- τ) produced by the embryo around the time of implantation. There is a high sequence homology of IFN- τ across ruminant species, where it apparently has a unique role in pregnancy initiation. One mechanism through which IFN- τ prolongs the function of the corpus luteum is by preventing high amplitude pulses of luteolytic PGF 2α . In many primates, from Old World monkeys to humans, embryonic trophoblast production of chorionic gonadotropin (CG) “rescues” the corpus luteum and extends luteal function in early pregnancy. CG binds to and signals through the same receptor that binds to LH. Similar to the gonadotropic hormones follicle stimulating hormone (FSH) and LH, CG is composed of a common alpha subunit as well as a unique beta subunit that is highly glycosylated and endows an increased half-life in the maternal bloodstream. After circulating CG is first detected around the time of implantation, its levels increase exponentially and peak in the first trimester. Administration of increasing amounts of recombinant human LH, as well as human CG, around the expected time of implantation increased progesterone levels and prevented timely luteolysis during the menstrual cycle in macaque monkeys. These data are consistent with the concept that CG’s ability to rescue the primate corpus luteum is due to differences in the circulating gonadotropin support; with LH being secreted in non-fecund cycles in intermittent pulses that result in periods (i.e., troughs) of LH deprivation, whereas CG levels increase continuously and at increasing levels in fertile cycles. Other studies have also provided evidence that CG signaling through the LH/CG receptor preferentially activates pathways responsible for promoting steroidogenesis, whereas LH is more potent in regulating the pathways that are important for cell survival during luteal development. By the end of the first trimester, the progesterone production needed to maintain pregnancy shifts from the corpus luteum to the placental trophoblast.

Summary and Future Research

Recent advances in methods that allow for genome-wide analyses are providing insight into the dynamic changes in corpus luteum gene expression that occur as a consequence of its development, function, regression during non-fecund cycles, as well as in response to fertilization and pregnancy. From these studies, there is now an unprecedented opportunity to carefully and systematically understand the coordinated events that dictate luteal structure and function. Potential areas of research that would benefit from recent high-throughput “omic” approaches include defining the underlying initiators and effectors of luteal regression in primate species as well as whether luteal regression after the luteal-placental shift is comparable to that occurring at the end of the non-fecund cycle. Due to the dynamic and ephemeral nature of the corpus luteum, there are also opportunities to understand basic biological processes relevant to various pathologies and diseases. For example, the corpus luteum offers a unique model for studying microvessel development, maintenance, and regression in a normal tissue. Based on the considerable amount of cholesterol required to support luteal progesterone production, the corpus luteum may also provide insight into the cellular processes that are important for cholesterol ester utilization and disposition. Studying the regression of the corpus luteum would also yield information regarding the processes involved in initiating cellular death and senescence.

It is obvious recent advances in reproductive and cell biology that are made from studying the corpus luteum are possible only because of the research conducted by the pioneers in the field that came before us. In this regard, acknowledgement of Drs. Gordon Niswender and William Hansel, both of which passed in 2017 is warranted. We owe them a great deal of gratitude for setting the foundation for our current understanding of corpus luteum biology.

Nomenclature

AKR1C3	Aldo-keto reductase family 1 member C3 (also known as PGFS and PTGFS)
ANGPT	Angiopoietin
ATF3	Activating transcription factor 3
cAMP	Cyclic adenosine monophosphate
CASP3	Caspase 3
CBR1	Carbonyl reductase 1
CCL	C-C motif chemokine ligand
CRE	cAMP response elements
CREB	cAMP responsive element binding protein
CYP11A1	Cytochrome P450 family 11 subfamily A member 1
CXCL	C-X-C motif chemokine ligand
EGR1	Early growth response 1
FOS	Fos proto-oncogene, AP-1 transcription factor subunit
LGALS	Galectin
ICAM1	Intercellular adhesion molecule 1
IFNG	Interferon gamma
IL	Interleukin
JUN	Fun proto-oncogene, AP-1 transcription factor subunit
KDR	Kinase insert domain receptor (also known as VEGFR2)
MAPK	Mitogen-activated protein kinases
NR4A1	Nuclear receptor subfamily four group A member 1
PG	Prostaglandin
PGF2A	Prostaglandin F2alpha
PTGFR	Prostaglandin F receptor
PROK1	Prokineticin 1
PTGS2	Prostaglandin-endoperoxide synthase 2
RIPK	Receptor interacting serine/threonine kinases
SELP	Selectin P
SERPINE1	Serpin family E member 1
SPP1	Secreted phosphoprotein 1
StAR	Steroidogenic acute regulatory protein
TGFB1	Transforming growth factor beta 1
THBS1	Thrombospondin 1
TNF	Tumor necrosis factor
TNFRSF1A	TNF receptor superfamily member 1A
VEGFA	Vascular endothelial growth factor A

Introduction

The corpus luteum (CL) is a transitory endocrine gland that forms on the ovary from the granulosa and thecal cells that remain in the postovulatory follicle. Its function is to secrete progesterone, preparing the uterus for implantation, as well as maintaining pregnancy by promoting uterine quiescence. If fertilization does not occur, or if embryonic signaling is insufficient, the CL will regress. Luteal regression (luteolysis) results in pregnancy failure, but also removes the negative feedback of progesterone on gonadotropin release, allowing for maturation and ovulation of a new follicle and another opportunity to establish a pregnancy. The ephemeral nature of the CL has intrigued scientists for decades and understanding the mechanisms responsible for luteolysis could shed light on the nature of cellular life or death in other tissues, including tumors. Although a viable CL is essential for reproduction in all mammals, the hormonal events that initiate luteolysis and the cellular mechanisms to sustain or overcome it remain at least

partially elusive. This article will highlight the established pathways leading to luteal regression or rescue. For more information and specific citations of work to elucidate luteolytic mechanisms, the reader is referred to previous reviews listed in the Bibliography for this article.

Initiation of Luteolysis

Luteolysis is the process by which functional and structural changes culminate in the rapid degradation and eventually, complete disappearance of the CL. The hallmark of luteolysis is the functional change that occurs, which is cessation of steroid production. This is followed by the somewhat more gradual structural changes, such as breakdown of extracellular matrix, cellular death, and removal of cellular debris. Hysterectomy prolongs the lifespan of the CL in sheep, cows, and guinea pigs, demonstrating that the uterus is necessary for normal timing of luteal regression. This is true for most species studied, albeit it is not the case in primates or dogs, in which hysterectomy does not alter ovarian cyclicity. In nonpregnant bitches, luteolysis appears to be a gradual degenerative process, whereas in pregnant, periparturient bitches, luteolysis is initiated by uteroplacental PGF₂A and progesterone declines more precipitously. The signal that initiates luteolysis in the primate is unknown. There is evidence that luteolysis results from decreased sensitivity of the CL to LH, but may also be initiated by a change in the balance of luteotropic (PGE₂) to luteolytic (PGF₂A) prostaglandins.

One of the major discoveries in reproductive biology during the middle of the 20th century was that the uterine luteolytic signal is prostaglandin F₂ α (PGF₂A). Estrogen from the developing preovulatory follicle stimulates PGF₂A release from the endometrium, with the effectiveness of estrogen being greater after a period of progesterone priming. Progesterone supports accumulation of prostaglandin precursor molecules in the endometrium and ultimately downregulates its own receptor, allowing for estrogen-stimulated expression of oxytocin receptors. A role for oxytocin in timing of luteolysis was first apparent when it was discovered that daily injections of oxytocin during the first week of the bovine estrous cycle resulted in premature regression of the CL and a shortened estrous cycle. Oxytocin infused into the uterus of cyclic ewes stimulates production of PGF₂A, with the greatest effect of oxytocin occurring near the end of the estrous cycle, and the least effect occurring in midcycle ewes. The pattern of endometrial expression of oxytocin receptors parallels uterine responsiveness to oxytocin, which explains why the uterus becomes more sensitive to the effects of oxytocin around the time of luteolysis. Further, after stimulation by oxytocin, the oxytocin receptors are internalized and recycled to the plasma membrane, a process that takes about 6 h, coinciding with the frequency of PGF₂A pulses from the endometrium. Oxytocin therefore serves as a pulse generator for uterine PGF₂A release.

The ruminant CL contains large concentrations of oxytocin. Oxytocin is synthesized and stored in the CL, and is released into the ovarian vein in response to PGF₂A. It was subsequently proposed that the oxytocin pulse generator that is operational during luteolysis involved a positive feedback loop between uterine PGF₂A and luteal oxytocin. In sheep, many of the oxytocin and PGF₂A (measured as the metabolite, 13,14-dihydro-15-keto-PGF₂A, or PGFM) pulses appear to be coincident, whereas in cows, only 50% of PGF₂A and oxytocin pulses are coincident. Continuous infusion or repeated injections of oxytocin in sheep late in the estrous cycle, which should downregulate oxytocin receptors, yielded contradictory results, with an increase in cycle length in one study but no effect in another study. Depletion of luteal oxytocin from the CL of cows also had no effect on estrous cycle length. Furthermore, it has been argued that concentration of luteal oxytocin at the end of the estrous cycle may be insufficient to promote uterine PGF₂A release, because the concentration of luteal oxytocin is greatest on days 5–10 of the estrous cycle and declines thereafter, decreasing before the decline in progesterone. The initial release of PGF₂A from the uterus is likely triggered by pituitary release of oxytocin and the contribution of luteal oxytocin to maintenance of PGF₂A pulses may differ somewhat between sheep and cows, and certainly between ruminants and nonruminants. Some of the controversial results may be due to subtle differences in timing or background concentrations of steroid hormones.

Treatment with progesterone on days 3–5 of the ewe estrous cycle causes premature upregulation of endometrial oxytocin receptors, PGF₂A release, and premature luteolysis, whereas a progesterone receptor antagonist administered on the same days delays luteolysis. Administration of the antagonist on days 12–14 similarly advances oxytocin receptor expression and uterine responsiveness to oxytocin, but the timing of luteolysis is unchanged. Progesterone administered to ewes on estrous cycle days 1–6 also decreases the content of luteinizing hormone (LH) receptors in the CL, and this action of progesterone can be prevented by administration of PGE₁ or PGE₂, resulting in normal luteal weights and estrous cycle lengths, despite progesterone-induced premature release of uterine PGF₂A. This implies that advancing the timing of luteolysis by progesterone involves not only changes in the oxytocin-PGF₂A pulse generator, but also changes within the CL that render it less sensitive to gonadotropins.

Acquisition of Luteolytic Capacity

The developing CL does not regress in response to PGF₂A, although it is not completely refractory to PGF₂A effects. The developing ruminant CL has a sufficient number of PGF₂A receptors and responds to PGF₂A with changes in gene expression, but these CL do not undergo luteolysis. On about day 6 in cows and sheep and day 13 in pigs, CL will regress in response to PGF₂A. This ability to undergo luteolysis in response to PGF₂A has been termed “acquisition of luteolytic capacity.” Unlike in ruminants, in pigs there is a marked increase in the number of PGF₂A receptors in the CL around the time of acquisition of luteolytic capacity. From a practical standpoint, the refractoriness of the early CL to the luteolytic effects of PGF₂A limits use of PGF₂A in estrous synchronization

protocols to the period of time after acquisition, but from a scientific perspective, the physiological differences in CL before and after acquisition have provided a useful model for understanding the changes that must occur for luteolysis to progress normally.

Differences in luteal responses to PGF_{2A} before and after acquisition of luteolytic capacity indicate that luteal prostaglandin metabolism, calcium signaling, and endothelial and immune cell responses to PGF_{2A} are likely critical mediators of the ability of the CL to undergo luteolysis in response to PGF_{2A}. Even with a double dose of PGF_{2A} given on Day 5, progesterone decreases but the CL fully recovers and is functional, indicating that the CL responds to PGF_{2A}, but is protected from its luteolytic effects. Prior to acquisition of luteolytic capacity, luteal endothelial cells do not respond to PGF_{2A} with changes in endothelin 1 or its receptors, as they do in CL with luteolytic capacity, nor do early CL produce cytokines in response to PGF_{2A}. Comparisons of Day 4 and Day 10 CL also indicate differences in the ability of PGF_{2A} to initiate signaling through calcium/calmodulin-dependent protein kinase kinase 2 (CAMKK2) and 5' adenosine monophosphate-activated protein kinase (AMPK), which may be necessary for luteolytic capacity. Genes related to immune responses, angiogenesis, and apoptosis were activated in mature CL by PGF_{2A}, but not in early CL. Thus, the ability of PGF_{2A} to cause luteolysis is dependent upon the development and maturation of endothelial and immune cells that, in addition to the steroidogenic cells, characterize the cellular makeup of the mature CL.

Once the CL has acquired luteolytic capacity, the progression of luteolysis depends on the PGF_{2A} concentration and pattern of pulsatility to which the CL is exposed. Administration of subluteolytic doses of PGF_{2A} to ruminants results in a transient decline in progesterone and reduction in luteal volume, but with no effect on the timing of luteal regression. The concentration of PGF_{2A} required to ensure luteolysis depends on the metabolic or reproductive state of the animal, because multiparous cows are less sensitive to PGF_{2A} than primiparous cows and pregnant sheep are less sensitive to PGF_{2A} than nonpregnant sheep. A luteolytic dose of PGF_{2A} will induce expression of immediate early genes that are a part of the luteolytic changes that occur in luteal cells, but without repeated exposure to pulses of PGF_{2A}, these transcripts decline in concentration and the CL is not committed to cell death pathways. The pulsatile pattern of PGF_{2A} release can be disrupted by selective inhibition of the prostaglandin transporter protein (PGT) in the endometrium, and this disruption extends the lifespan of the CL.

Experiments with unilaterally hysterectomized ewes and heifers during normal and oxytocin-induced luteolysis revealed that the retained uterine horn must be ipsilateral to the ovary bearing the CL in order for regression to occur, indicating that the effect of the uterus to initiate luteolysis required a local mechanism of transport of PGF_{2A}. Prostaglandin travels from the uterus to the ovary via counter-current transfer across the anastomoses of the uterine vein and ovarian artery. In sheep, approximately 97% of the PGF_{2A} released from the uterus into the general circulation is metabolized after just one passage through the lungs, making counter-current transport critical for luteolysis. In cows, less, but still greater than 50%, of the PGF_{2A} is quickly metabolized, so delivery of the large concentrations of PGF_{2A} necessary for luteolysis also relies on counter-current transfer in this species. The counter-current mechanism is accomplished by expression of prostaglandin transporter (PGT) in the tunica intima, tunica media, and tunica adventitia of the uteroovarian vein and the ovarian artery. PGT is a 12-membrane-spanning protein that mediates the movement of prostaglandin through cellular membranes, and in this case, across the endothelium from the uterine vein to the ovarian artery.

Although uterine PGF_{2A} does not initiate luteolysis in the primate, withdrawal of gonadotropin support can cause luteolysis, but restoration of gonadotropin results in recovery of the CL, with normal concentrations of progesterone and luteal lifespan. This, coupled with the response of the ruminant CL to subluteolytic doses of PGF_{2A}, indicates that the early stages of luteolysis, as manifested by the initial decline in progesterone, are reversible.

PGF_{2A} Signaling in the Corpus Luteum

The ability of PGF_{2A} to cause luteolysis is dependent on activation of multiple intracellular events within the steroidogenic cells to reduce progesterone secretion, as well as activation of nonsteroidogenic cells to facilitate cellular death and structural degradation of the tissue. In the CL, PGF_{2A} binds to a G protein coupled receptor in the plasma membrane (PTGFR) and initiates luteolysis by activation of phospholipase C, which cleaves inositol triphosphate and diacylglycerol from membrane phospholipids, leading to an increase in intracellular free calcium and activation of protein kinase C. The functional effects of PGF_{2A} (inhibition of steroidogenesis) are mediated by activation of the protein kinase C pathway. The actions of PGF_{2A} are thought to be primarily on the large luteal cells, which contain many PTGFR, although the small steroidogenic cells, as well as endothelial and immune cells, can express PTGFR. PGF_{2A} directly inhibits LH-stimulated progesterone production in cultured steroidogenic luteal cells from rats, ewes, and cows. The PGF_{2A}-induced decrease in progesterone is likely due to an uncoupling of the mechanism by which cholesterol moves to, or associates with, the cholesterol side-chain cleavage enzyme, CYP11A1. This enzyme is located in the mitochondria and converts cholesterol to pregnenolone, the immediate precursor of progesterone. Association of cholesterol with CYP11A1 is the rate-limiting step in steroidogenesis, which makes it a perfect target to achieve a rapid loss of progesterone production. When cultured bovine luteal cells are treated with PGF_{2A}, cholesterol transport to the mitochondria is not disrupted, but the cholesterol is not converted to progesterone. However, side-chain cleavage of 25-OH-cholesterol, which is readily diffusible across membranes, is not inhibited by PGF_{2A}. Therefore, the acute effect of PGF_{2A} may be to prevent movement of cholesterol from the outer to the inner mitochondrial membrane. The StAR protein mediates cholesterol transfer in the mitochondria. Progesterone declines prior to the decrease in StAR mRNA or protein content, but this does not rule out an effect of PGF_{2A} on the process of StAR-mediated cholesterol transfer. The exact mechanism by which PGF_{2A} disrupts cholesterol transfer or metabolism in the mitochondria is unknown.

The activation of protein kinase C induced by PGF2A leads to activation of mitogen-activated protein kinase (MAPK) signaling pathways, including MAPK3 (ERK1/2), MapK8 (JNK), MAPK11 (p38) and ATF3, and upregulation of the transcription factors, Fos, Jun, NR4A1, and EGR1. ATF3 inhibits LH-induced progesterone synthesis by binding to CRE, the transcription factor that is activated by the cAMP/protein kinase A signaling pathway. Activation of MAPK11 and MAPK8 have been linked to regulation of apoptosis and autophagy, and to stimulation of interleukin (IL)8, which serves as a chemoattractant to neutrophils during luteolysis. Gene expression studies have indicated that early changes in luteolysis likely involve immune response, cytokine signaling and cell death pathways, whereas later in luteolysis, genes associated with regulation of cholesterol and steroid biosynthesis predominate.

Upon initiation of luteolysis by PGF2A, there is autoamplification of the PGF2A signal in luteal cells. PGF2A stimulates the enzymes that metabolize arachidonic acid and PGH2–PGF2A (PTGS2 and AKR1C3, respectively), or convert PGE2–PGF2A (CBR1), but downregulate the enzymes that catabolize PGF2A to inactive metabolites. PGE2 activates the cAMP pathway in luteal cells, stimulating progesterone production. Thus, conversion of PGE2–PGF2A may be important to maintain the decline in steroidogenesis. This may be especially critical for luteolysis in species such as primates, in which uterine PGF2A is not required for luteolysis. The high concentrations of progesterone that are present in the CL prior to luteolysis reduce luteal prostaglandin synthesis, but the initial decline in progesterone allows for the autoamplification of PGF2A. In pigs, inhibition of progesterone production prior to the onset of luteolytic capacity allows for exogenous PGF2A to elicit some luteolytic responses. Thus, the life or death of the CL depends, in part, on the balance of progesterone and prostaglandin synthesis that occurs within the CL itself.

Increased concentrations of Ca^{2+} in response to PGF2A lead to upregulation of CAMKK2, which phosphorylates AMPK. Downstream effects of this pathway are reduced expression of the low density lipoprotein receptor and an increase in acyl coenzymeA: cholesterol acyltransferase (ACAT1), which collectively make free cholesterol less available for conversion to pregnenolone. By 12 h after the initiation of luteolysis, genes responsible for cholesterol uptake are downregulated, whereas genes responsible for cholesterol efflux are upregulated. Thus, as cholesterol balance is a critically important feature of the maintenance of steroidogenesis, disruption of cholesterol supply to the cells is also part of the mechanism to reduce steroidogenesis.

The conversion of cholesterol to pregnenolone and the high metabolic activity of luteal cells results in mitochondrial production of free radicals, which have negative effects on both progesterone production and cell viability. Prior to luteolysis, the reactive oxygen species may be neutralized by high concentrations of antioxidant enzymes and lipids, such as glutathione peroxidase and beta-carotene. Recently, it has been demonstrated that lysophosphatidic acid (LPA) completely prevents reactive oxygen species-induced decreases in progesterone production and stimulation of apoptosis. Reactive oxygen species are also produced by luteal endothelial cells and mediate some of the luteolytic effects of PGF2A. Superoxide dismutase concentration and activity is increased by a direct action of PGF2A on endothelial cells, and hydrogen peroxide further enhances PGF2A production by endothelial cells. Therefore, this provides another positive feedback loop to advance luteolysis. Conversely, progesterone suppresses nitric oxide production by luteal endothelial cells, perhaps protecting the CL from premature luteolysis while progesterone is elevated. The intracellular pathways and known downstream mediators of PGF2A signaling in luteal steroidogenic cells are depicted in Fig. 1.

During PGF2A-induced luteolysis, concentrations of VEGFA and ANPT1 in the CL decrease, whereas concentrations of TGFB1 and ANPT2 increase. This leads to destabilization of blood vessels. In fact, capillary endothelial cells are the first cells in the CL to undergo degenerative changes, although the decline in progesterone production by steroidogenic cells precedes the decline in blood flow to the CL, reinforcing the concept that luteolysis is achieved by a multifactorial insult from PGF2A. Another effect of TGFB1 during luteolysis is to promote conversion of fibroblasts to myofibroblasts and the formation of arteriovenous anastomoses, limiting nutrient supply to the extravascular cells. Lymphoangiogenic factors are downregulated by PGF2A, indicating that there is a simultaneous breakdown of the draining lymphatic vessels in addition to the capillary vasculature in the CL.

Recent evidence indicates that viability of luteal cells may be regulated by galectins (LGALS) and by thrombospondin 1 (THBS1). Galectin 1, which binds to glycans on KDR and supports viability of steroidogenic cells, is decreased in regressing corpora lutea. Conversely, LGALS 3 expression is increased by PGF2A during luteal regression. LGALS binds to beta 1 integrin, with a downstream effect of caspase 3 (CASP3) cleavage, resulting in decreased cell viability, but with no direct effect on the steroidogenic pathway. Further, alpha 2,6-sialylation of glycoproteins is increased in response to PGF2A during luteolysis, and this prevents binding of LGALS. For this reason, LGALS1 cannot support viability of late stage luteal steroidogenic cells. Thus, the balance of LGALS1 and LGALS3, and the degree of alpha 2,6-sialylation of glycoproteins may be important regulators of life or death of the steroidogenic cells. Apoptosis of steroidogenic cells is also directed by THBS1, which is increased during luteolysis and activates CASP3. THBS1 also increases expression of TGFB1, which stimulates expression of SERPINE1, facilitating breakdown of extracellular matrix.

In addition to apoptosis, luteolysis may involve both autophagy and programmed necrosis. Within 4 h of PGF2A treatment, the sensors of cellular stress, RIPK1 and RIPK3, are increased in concentration. These proteins are stimulated by TNF and IFNG and lead to necroptotic cell death. Progesterone can prevent apoptosis in luteal steroidogenic cells, but may not be a regulator of programmed necrosis because inhibition of RIPK1 by necrostatin 1 increases cell viability, with no effect on progesterone or caspases. The different pathways by which cell death occurs during luteolysis may be related to the heterogeneous cell types in the CL.

Fig. 1 Mechanisms of prostaglandin $F_{2\alpha}$ (PGF $_{2\alpha}$) action in steroidogenic cells of the CL. PGF $_{2\alpha}$ binds to a receptor (PTGFR) located in the plasma membrane of cells. Activation of phospholipase C (PLC) leads to generation of inositol triphosphate (IP3) and diacylglycerol (DAG), leading to an increase in intracellular calcium and activation of protein kinase C (PKC). Increased concentration of CAMKK2 (calcium/calmodulin-dependent protein kinase kinase 2) results in phosphorylation of adenosine monophosphate kinase (AMPK), leading to decreased expression of low density lipoprotein receptor (LDLR) and scavenger receptor class B member 1 (SCARB1) and increased concentration of acyl coenzymeA: cholesterol acyltransferase (ACAT1) and ATP binding cassette subfamily A member 1 (ABCA1). Collectively, these changes lead to reduced cholesterol availability in luteal cells. Activation of map kinases (MAPK1, MAPK8, and MAPK11) causes upregulation of a number of transcription factors that regulate genes responsible for apoptosis, inflammation and cholesterol homeostasis. One such factor, ATF3 prevents CREB (cAMP responsive element binding protein) binding to CRE (cAMP responsive element), which inhibits LH-stimulated progesterone production. MAPK8 leads to increased synthesis of interleukin (IL)8, which activates neutrophils and promotes migration into the CL. An important effect of PGF $_{2\alpha}$ in luteal cells is to prevent association of cholesterol with the cytochrome P450 side-chain cleavage enzyme (CYP11A1), although the mechanism for this action of PGF $_{2\alpha}$ is unknown. Excessive production of reactive oxygen species (ROS) during luteolysis likely contributes to apoptosis and promotion of an inflammatory response. Finally, activation of phospholipase A2 (PLA2) causes membrane phospholipids to be converted to arachidonic acid, which is the precursor for prostaglandin synthesis. PGF $_{2\alpha}$ stimulates prostaglandin synthase 2 (PTGS2) and prostaglandin F synthase (AKR1C3), as well as carbonyl reductase 1 (CRB1), which results in increased synthesis of PGF $_{2\alpha}$ and a decrease in the ratio of PGE2 (a luteotropic prostaglandin) to PGF $_{2\alpha}$ (a luteolytic prostaglandin). Together, the cascades of signaling events that are initiated by PGF $_{2\alpha}$ in the CL lead to acute inhibition of progesterone production, activation of immune cells, chronic reduction in cholesterol availability for steroidogenesis and apoptosis of endothelial and steroidogenic cells. (Dashed lines indicate multiple steps).

Participation of Nonsteroidogenic Cells in Luteolysis

The direct action of PGF $_{2\alpha}$ to initiate luteolysis is the inhibition of steroidogenesis. Although some of the biochemical changes in luteal cells may promote cell death, a direct effect of physiological concentrations of PGF to initiate cell death in isolated steroidogenic cells has not been demonstrated. The CL is comprised of a heterogeneous population of cells, with capillary endothelial cells being particularly abundant, a network of fibroblasts that develop the supporting extracellular matrix and immune cells scattered throughout the luteal tissue. These cells participate in the luteolytic process. PGF $_{2\alpha}$ stimulates production of endothelin-1 by capillary endothelial cells, which inhibits progesterone production by steroidogenic cells. Cooperative interaction among steroidogenic cells, immune cells and endothelial cells occurs to ensure the progression of luteolysis by recruiting additional immune cells and orchestrating the destruction of the tissue itself.

Immune cells are present in the CL when it is fully functional. Macrophages are necessary for proper angiogenesis during luteal development, and immune cells may facilitate extracellular matrix remodeling and homeostasis of the metabolically active tissue. However, during luteolysis, chemokines (CCL2, CCL8, CXCL2, SPP1, and IL8), and adhesion molecules (SELP, ICAM1, and PROK1) are increased and recruit additional macrophages, T lymphocytes, and neutrophils into the CL. There is evidence of spatial regulation of macrophage recruitment into the human CL, with more abundant macrophages located in areas that lack the enzymes for production of progesterone or PGE, suggesting that these molecules may suppress local immune cell trafficking. Adhesion of

immune cells to bovine luteal endothelial cells is reduced when progesterone concentration is high, but the decline in progesterone early in luteolysis may allow for extravasation of immune cells.

The immune cells produce cytokines, such as TNF, IFNG, and IL1B, which inhibit progesterone production and stimulate prostaglandin production by luteal steroidogenic cells. The latter effect of the cytokines further contributes to the amplification of PGF2A production in luteal cells. TNF and IFNG also modify synthesis of prostaglandins, leukotrienes and endothelins, and promote nitric oxide production in luteal endothelial cells. Expression of both TNF and TNFRSF1A becomes widespread on many types of cells in the CL during luteolysis. TNF and IFNG promote apoptosis of luteal steroidogenic and endothelial cells. IFNG also contributes to structural degradation of the CL by activation of matrix metalloproteinases, resulting in breakdown of the extracellular matrix. TNF is an obligatory component of the luteolytic cascade, because PGF2A fails to induce luteolysis in either TNFRSF1A null mice or in mice treated with TNF antibody.

The immune cells in the regressing CL are distinct from those in the fully functional CL. The immune cells that reside in the functional CL may exit and be replaced with alternative cell types during luteolysis, or more likely, these immune cells are induced to change their function by the luteal microenvironment. Although it was once thought that immune cell phenotype was fixed, it is now widely recognized that many immune cells can exhibit phenotypic plasticity. In coculture experiments, luteal steroidogenic and endothelial cells altered the expression of immune cell membrane and secreted proteins, indicating that the parenchymal cells could program immune cells toward a particular functional phenotype. In the primate CL, the luteal-resident macrophages and neutrophils produce more cytokines/chemokines after progesterone has declined compared to when the CL is fully functional. In the bovine CL, there is a decline in the proportion of regulatory T cells during luteolysis, and a robust upregulation of the CD8 $\alpha\alpha$ homodimer on CD8⁺ T cells in the CL by 8 h after exposure to PGF2A. This represents a shift from suppression of an inflammatory response in the functional CL, to resolution of an inflammatory response in the regressing CL. Studies of acute changes in mRNA in the CL indicate that proinflammatory cytokines may be early mediators of luteolysis, but it would be detrimental to ovarian function if such a response was maintained. Thus, functional changes in immune cells are necessary to resolve any inflammatory process that was initiated during luteolysis. Cellular interactions and mediators of luteal regression are highlighted in Fig. 2.

Luteal Rescue

The transitory nature of the CL is necessary to allow for repeated opportunities for fertilization, because follicular maturation and ovulation are usually suppressed when progesterone concentrations are high. However, if fertilization has occurred, it is essential that the CL be maintained. Therefore, most species that rely on the CL for pregnancy maintenance have developed mechanisms by which signals from the developing embryo result in rescue of the CL from luteolysis. Prevention of luteolysis by embryonic signals in early pregnancy has been termed “maternal recognition of pregnancy.”

In species in which uterine PGF2A initiates luteolysis, rescue of the CL involves changes in uterine secretion of PGF2A, and the ratio of PGE2–PGF2A released from the uterus is greater than that observed during luteolysis. In ruminants, these changes are in response to embryonic secretion of a Type I interferon, IFN τ (IFNT), which acts on endometrial cells to inhibit expression of estrogen receptors. The lack of estrogen action in the endometrium results in less expression of oxytocin receptors, which disrupts the normal pulsatile release of PGF2A that is necessary to cause luteolysis. In pigs, the pregnancy recognition signal is estrogen, which redirects endometrial PGF2A from endocrine (into the uterine vein) to exocrine (into the uterine lumen) secretion. Equine embryos migrate between the two uterine horns and presumably signal to the endometrium, because there is lesser expression of oxytocin receptors and prostaglandin synthase 2 than observed in cyclic mares, and PGF release is not pulsatile. However, the identity of the embryonic signal in the mare is unknown. In primates, the embryonic trophoblast produces chorionic gonadotropin, which directly provides gonadotropic support and stimulation of steroidogenesis in the CL. In the domestic dog, no embryonic signal is required to maintain the CL, because the CL of a nonfertile cycle is maintained beyond that of a CL of pregnancy.

Rescue of the CL also involves mechanisms within the tissue to maintain steroidogenesis and capillary integrity. During maternal recognition of pregnancy, the CL becomes less sensitive to the luteolytic effects of PGF2A, and the autoamplification of PGF2A that occurs during luteolysis is prevented by inhibition of AKR1C3 and stimulation of the enzymes that convert PGF2A to inactive metabolites. Luteal cells *in vitro* are responsive to IFNT, and during the period of maternal recognition of pregnancy, interferon-stimulated genes (ISG) are expressed in the CL. Some IFNT does exit the uterus to enter the general circulation and may reach the CL, although the amount and role of embryonic IFNT within the CL is controversial. Circulating white blood cells also express ISG in response to embryonic IFNT. During maternal recognition of pregnancy there is a transient influx of neutrophils into the CL, so it has been proposed that IFNT-activated neutrophils may induce the changes in ISG that are observed in the CL.

The CL of pregnancy is protected from effects of oxygen radicals by maintenance of antioxidant enzymes and synthesis of lysophosphatidic acid (LPA). LPA also stimulates synthesis of PGE2, which protects the CL from oxytocin-induced luteolysis, possibly by preventing loss of LH receptors to maintain steroidogenesis. Small noncoding RNA (microRNA) that regulate protein synthesis are differentially expressed in the CL of pregnancy compared to the CL of the cycle, indicating these molecules may support intracellular pathways that result in cell survival. Based on *in silico* analyses of luteal microRNA, they likely regulate immune cell functions within the CL of early pregnancy. This is supported by the observation that immune cell phenotype is altered in the CL of pregnancy compared to the CL of the cycle. Although the exact cellular interactions and intracellular biochemical pathways have

Fig. 2 Changes that occur in the CL during luteolysis. Functions of luteal endothelial cells (LEC) change early in luteolysis. LEC produce endothelin 1 (EDN1), which acts on luteal small and large steroidogenic cells (LSC) to decrease progesterone production. Endothelial cell expression of chemokines (CCL2, CCL8, CXCL2) and adhesion molecules (SELP, ICAM1, PROK1; see nomenclature), results in recruitment of immune cells and extravasation into the luteal parenchyma, where they can be in intimate contact with LSC. There is decreased expression of growth factors (VEGFA, ANPT1) in the CL, which results in destabilization of blood vessels and disruption of blood flow. Thrombospondin 1 (THBS1) is produced by both LEC and LSC and has multiple effects in the CL during luteolysis, leading to activation of caspase 3, which is part of the apoptotic cascade, and to increased expression of transforming growth factor beta 1 (TGFβ1). TGFβ1 increases synthesis of SERPINE1, facilitating breakdown of the extracellular matrix (ECM). TGFβ1 also causes transformation of fibroblasts into myofibroblasts, which leads to formation of arteriovenous anastomoses in the CL during luteolysis, decreasing oxygen availability to the luteal cells. Activated immune cells in the CL produce cytokines (TNF, IFNG, IL1B) that inhibit LH-stimulated progesterone and stimulate PGF2A production in LSC, promote production of reactive oxygen species (ROS) and ECM breakdown, and cause apoptosis of LSC. TNF also stimulates receptor interacting serine/threonine kinases (RIPK1, RIPK3), which promote another cellular death pathway, necroptosis. There are also changes in the phenotype of T cells (TC) in the CL. Loss of FoxP3⁺ cells and increased surface expression of the CD8αα/CD8αβ heterodimer indicates a shift from suppression of a proinflammatory response to resolution of the transient proinflammatory response that occurs early in luteolysis. Although the localization of some events in a particular cell type is as yet undefined, it is clear that each of these types of cells plays a role in orchestrating the changes associated with regression of the CL.

yet to be elucidated, ultimately the signal from the embryo results in maintenance of survival genes and prevents upregulation of death pathway-related genes, protecting the integrity of the luteal vasculature and maintaining steroidogenesis. This event is critical for successful reproduction, so future studies to understand the mechanisms associated with luteal rescue are of the utmost importance.

Glossary

Corpus luteum A yellow ovarian endocrine structure formed after the oocyte is released and composed of transformed granulosa cells and theca interna cells that secretes progesterone and oxytocin.

Decidualization Process that results in significant morphological and functional changes in endometrial stromal cells under the influence of progesterone during the luteal phase of the cycle.

Endometrium The mucosal lining of the uterus consisting of glandular epithelium and stroma.

Estradiol The predominant estrogen produced by the granulosa cells of the ovarian follicle from androgen precursors. Estradiol is an 18'carbon steroid.

Follicle A spherical structure in the ovary that contains an oocyte surrounded by granulosa cells, theca interna and theca externa. Follicles will progress from primordial to primary, secondary, and finally antral follicles.

Follicle stimulating hormone (FSH) A pituitary glycoprotein hormone that initiates and sustains follicle development and steroidogenesis.

Follicular phase The phase of the estrous cycle characterized by the presence of a dominant follicle that produces estradiol. It is the period before ovulation.

GnRH pulse generator A group of endogenously pulsatile interconnected neurons located in the mediobasal hypothalamus that synthesize and release GnRH into the portal vasculature to thereby stimulate pituitary gonadotropins synthesis and secretion.

Gonadotropins The hormones FSH and LH are the two gonadotropins produced by the gonadotropes in the anterior pituitary. These are both glycoprotein hormones consisting of a common alpha subunit and a unique beta subunit. Both hormones are regulated by GnRH from the hypothalamus.

Hypothalamus Part of the brain located around the inferior portion of the third ventricle. It receives ascending neural signals from the brain stem and descending neuronal input from the limbic lobe and frontal cortex and projects primarily to the median eminence and posterior pituitary.

Kisspeptin A protein hormone that plays an important role in initiating the secretion of GnRH from the hypothalamus. Kisspeptin producing neurons are located in the anteroventral periventricular nucleus and in the arcuate nucleus.

Luteal phase The second half of the cycle following the LH surge and ovulation, which is characterized by progesterone dominance and the presence of a functional corpus luteum. The luteal phase begins after ovulation and ends when the corpus luteum regresses.

Luteinizing hormone (LH) A pituitary glycoprotein hormone that is produced by the gonadotropes. LH has two main functions in the ovary; (1) to stimulate theca cells of the ovary to secrete androgens including androstenedione; and (2) to cause ovulation of ovarian follicles and formation of the corpus luteum.

Ovary The female gonad that is the source of oocytes needed for reproduction in the female.

Pituitary Endocrine gland that consists of the anterior and intermediate glandular lobes and the neurohypophysis or neural lobe. It is connected to the hypothalamus by the hypothalamo-hypophyseal-portal blood system.

Progesterone A 21'carbon steroid made and secreted by the corpus luteum in high concentrations after ovulation for approximately 14 days. Progesterone is required for maintenance of pregnancy.

Proliferative phase Endometrial events that occur during the first half of the menstrual cycle, namely the proliferation and growth of the endometrium in response to sustained exposure to estradiol.

Secretory phase Endometrial events that occur during the second half of the menstrual cycle, when the endometrial glands gain full secretory activity in response to progesterone and estrogen.

Estrous Cycles

Unlike mature male mammals, where gametogenesis and steroidogenesis occur continuously throughout life, females exhibit repetitive cyclic changes that occur either as estrous cycles or menstrual cycles. This reproductive cyclicity is initiated after puberty and allows female mammals with repeated opportunities to copulate, conceive, and bear offspring. The cyclic nature of reproduction in female mammals depends on carefully coordinated cyclic changes in the hypothalamic-pituitary-ovarian axis which result in the production of both mature oocytes and a uterine environment that is prepared to support a conceptus should fertilization occur. Estrous or menstrual cycles will be interrupted by pregnancy and lactation and occur in seasonal breeders only during a specific time of the year that is dependent on daylength.

The beginning of the estrous cycle is the period when the female is sexually receptive (known as estrus or heat) and this stage is soon followed by ovulation of one or more follicles. The overall length of an estrous cycle is measured from one period of estrus to the next succeeding period of estrus. Each estrous cycle can be divided into two main phases, the follicular phase and the luteal phase. The follicular phase of the cycle is dominated by the actions of the ovarian steroid hormone estradiol, whereas the luteal phase is dominated by the steroid hormone progesterone produced by the corpus luteum. Estrous cycles can be very short, lasting only 4–5 days in rodents, or last for much longer periods ranging from 17 to 21 days for most domestic production animals.

Estrous cycles in rodents can be divided into four stages called proestrus, estrus, metestrus, and diestrus each of which last approximately 1–2 days. Proestrus is the stage right before estrus. It is the time during which the corpus luteum undergoes luteolysis resulting in a sharp decline in progesterone, allowing for increases in follicle stimulating hormone (FSH) and luteinizing hormone (LH) which lead to increased estradiol production by ovarian follicles. Estrus then occurs in response to the increasing estradiol levels causing the female to become sexually receptive to the male and this is soon followed by ovulation. Metestrus is the period of transition between ovulation and the formation of the functional corpus luteum. The formation of the corpus luteum from the follicle wall involves significant tissue and cell remodeling and is called luteinization. The final stage of the estrous cycle in rodents is called diestrus and is the period when the completely functional corpus luteum is secreting high amounts of progesterone. If no conceptus is present, the corpus luteum will undergo regression and the female will enter proestrus, the beginning of the next cycle.

The duration of the estrous cycle in domestic animals such as the cow, sow, and mare average 21 days in length whereas the cycle is 17 days in the ewe (see [Table 1](#)). Estrus, the time during which the female is receptive to mating with the male, is variable in length within species. Ruminants such as the cow and ewe experience short estrus periods of 29 h or less while species such as the sow and mare show estrus periods of several days. The cow and sow are polyestrous, with a number of estrous cycles occurring each year, whereas the mare and ewe are seasonally polyestrous. The mare is a long day breeder exhibiting estrous cycles in spring and summer while the ewe is a short day breeder with cycles occurring in the late summer and fall. Some species such as the dog, wolf, and bear experience only one estrous cycle each year and are called monoestrous.

The estrous cycle in domestic animals is divided into two unequal phases ([Fig. 1A and B](#)). The first is the relatively short follicular phase which is the period of rapid follicular development beginning with regression of the corpus luteum of the previous cycle and ending with estrus and ovulation of one or more follicles. The second is the much longer luteal phase which extends from the formation of the corpora lutea after ovulation until their regression at the end of the cycle. The estrous cycle of domestic animals differs from that in rodents due to the fact that rodents lack a true luteal phase. The corpus luteum that forms after ovulation in the absence of mating is very short-lived, lasting only 1–2 days. If mating does occur, the corpus luteum will secrete progesterone for a length of time comparable to that of the corpus luteum of domestic animals. This extended lifespan of the corpus luteum is called pseudopregnancy and also occurs in other species such as rabbits and dogs.

Reproductive Hormones Throughout the Estrous Cycle

The reproductive hormones that regulate ovarian cyclicity show a characteristic ebb and flow which is schematically illustrated in [Fig. 1A](#). The two pituitary gonadotropin hormones luteinizing hormone (LH) and follicle stimulating hormone (FSH) are important regulators of follicular development, ovarian steroidogenesis, and ovulation. The levels of LH are relatively low during the luteal phase and FSH levels follow a similar pattern to LH with a modest rise during the time of luteal regression. These basal levels of gonadotropins are needed to initiate the next round of follicular development. As the ovary enters the follicular phase, and the follicle(s) begin to grow rapidly, estradiol synthesis will increase leading to a marked rise in circulating estradiol levels. Estradiol levels will peak prior to or at the onset of estrus. It is this rise in estradiol levels that leads to the LH surge and ovulation. FSH levels

Table 1 Average reproductive cycles

Species	Length of estrous cycle	Length of estrus	Ovulation	Length of pregnancy
Cow	21 days polyestrous	18 h	11 h after end estrus	282 days
Ewe	17 days seasonal (fall)	29 h	Near end estrus	148 days
Sow	21 days polyestrous	48–72 h	35–45 h after start estrus	115 days
Mare	21 days seasonal (spring) polyestrous	4–8 days	3–6 day of estrus (1–2 days before end of estrus)	335 days

Fig. 1 Schematic outline of ovarian events and changes in reproductive hormone levels throughout the estrous cycle. (A) corpus luteum (CL) regresses to form corpus albicans (CA). New follicles develop, ovulate and form new corpora lutea. Changes in the hormones progesterone, estradiol, prostaglandin F₂ α (PGF₂ α), follicle stimulating hormone (FSH) and luteinizing hormone (LH) are depicted. Day 0 is the day of the LH surge/ovulation. (B) The *shaded areas* represent the luteal phase of the estrous cycle, the *unshaded area* is the follicular phase of the estrous cycle.

also show a peak during this peri-ovulatory period. Once the follicle(s) has ovulated, it will form a corpus luteum which will begin to produce progesterone to prepare the uterus for implantation of a conceptus.

The corpus luteum is formed from the granulosa cells remaining in the follicle wall and by theca interna cells that penetrate into the granulosa layer. These two cell types of the corpus luteum become large (from granulosa) and small (from theca interna) luteal cells and synthesize progesterone. Progesterone levels begin to rise soon after ovulation with a noticeable increase in concentrations beginning days 3–4 after ovulation and they remain elevated for the duration of the lifespan of the corpus luteum. The rapidity with which progesterone secretion rises after ovulation and the maximum levels reached are proportional to the number of corpora lutea in litter bearing animals such as the pig. If no pregnancy occurs, luteolysis will occur in response to increases in circulating levels of prostaglandin F₂ α coming primarily from the uterus in the domestic animal species. The increase in prostaglandin production by uterine epithelial cells occurs in response to oxytocin. In the absence of a conceptus, oxytocin receptors are induced in the uterine epithelial cells and episodic pulses of oxytocin secretion from the ovary then become coupled with the release of prostaglandin F₂ α (PGF₂ α) from the uterus. If a conceptus is present, luteal regression will not occur due to production of an anti-luteolytic factor by the conceptus. This anti-luteolytic factor will prevent oxytocin receptor expression in uterine epithelial cells and consequently the pulsatile pattern of PGF₂ α secretion needed to achieve luteolysis. These anti-luteolytic factors have been identified in some domestic animal species and include interferon-Tau in cattle and sheep, estrogens in pigs, and a mix of small proteins in the mare.

Hypothalamic-Pituitary–Ovarian Axis

The pattern of regular ovulatory cycles is dependent on a complex and tightly regulated interplay between the hypothalamus, pituitary, and ovary, which together make up the reproductive axis. The cyclic changes in the pituitary gonadotropins and in the ovarian

steroid hormones are the result of negative and positive feedback effects of the ovarian hormones estradiol and progesterone on the hypothalamus and pituitary gland. The reproductive system functions in a classic endocrine mode initiated by pulsatile secretion of gonadotropin releasing hormone (GnRH) from the hypothalamus into the pituitary portal venous system. GnRH regulates the synthesis and release of both FSH and LH from the gonadotropes of the anterior pituitary. FSH and LH secretion differ somewhat throughout the cycle and this differential regulation of the two hormones produced by the same cells occurs in response to changing pulse frequencies of GnRH. A rapid pulse frequency favors LH synthesis and secretion while a slower pulse frequency favors the production of FSH.

The key unique feature of ovarian steroid hormone regulation of the ovulatory cycle is that estradiol is able to exert both inhibitory and stimulatory effects on LH secretion. The direction of estradiol feedback is dependent on both the levels of estradiol and duration of exposure with low levels of estradiol inhibiting LH secretion, while positive feedback of estradiol occurs in response to higher concentrations over a more prolonged duration. The negative feedback effects of estradiol occur at the level of the hypothalamus resulting in a decreased amplitude of GnRH pulses. Estradiol exerts positive feedback effects at the level of the hypothalamus and also directly on the pituitary. As the follicular phase progresses and ovarian follicles produce more and more estradiol, the sustained rise in estradiol leads to the positive feedback effect on LH secretion. This positive feedback effect of estradiol is manifested at the hypothalamus as increased frequency and amplitude of GnRH pulses. In addition, there is a positive feedback effect directly at the pituitary with a 20-fold increase in sensitivity of the pituitary gonadotropes to GnRH resulting in a marked increase in LH synthesis and secretion. The positive feedback effect of rising estradiol in the hypothalamus occurs through the kisspeptin neurons. GnRH neurons do not express estrogen receptors but the kisspeptin neurons do. In the female there are two kisspeptin neuron nuclei as compared to only one in the male. The second kisspeptin neuron nucleus is called the surge center and it is this cluster of kisspeptin neurons that responds to the positive feedback effect of estradiol leading to stimulation of pulsatile GnRH secretion. The result of the positive feedback effect of estradiol on the hypothalamus and pituitary is initiation of the ovulatory LH surge. A small rise in FSH occurs simultaneously with the marked rise in LH at ovulation. Following ovulation, the corpus luteum forms and begins to produce significant quantities of progesterone and also low levels of estradiol. Progesterone exerts a very strong negative feedback effect on the hypothalamic GnRH pulse generator causing GnRH pulse frequency to slow dramatically. The inhibitory effect of progesterone on GnRH neurons is mediated through the production of the endogenous opioid β -endorphin in the brain. The sustained levels of progesterone will inhibit LH and FSH secretion during the luteal phase. Once luteal regression is initiated and progesterone levels begin to fall, FSH levels will begin to rise and initiate a new round of follicular development.

Menstrual Cycle

The menstrual cycle in women and non-human primates differs from the estrous cycles of domestic mammals in that the follicular phase is much longer, lasting about 2 weeks. The length of the luteal phase (about 2 weeks) in women is similar to that of domestic animals. In addition, only women and non-human primates undergo the cyclic shedding of the endometrium during menstruation. The human menstrual cycle can be divided into three phases based on functional and morphological changes in the ovary and uterus (Fig. 2A and B). These three phases are (1) the menstrual phase also called menses; (2) the follicular phase also called the proliferative phase; and (3) the luteal or secretory phase. The terms proliferative and secretory refer to the fact that the uterine epithelial cells in the endometrium are undergoing marked proliferation during the follicular phase while during the luteal phase they become highly differentiated and secretory. These changes in the endometrium during the menstrual cycle are dependent on the ovarian hormones estradiol and progesterone and are exquisitely timed so that they can be used to document the day of ovulation. Endometrial biopsies are typically taken during the secretory phase where the histological changes can be used to accurately date the cycle to within a day. It is customary to designate the first day of the cycle (day 1) as the first day of the menstrual phase (i.e., when menstruation begins). The menstrual cycle averages 28 days in length. However, only about 10%–20% of menstrual cycles are exactly 28 days. Cycle length can vary greatly among different women and may also vary significantly in a single woman. Most cycle are between 25 and 30 days long, but some women experience cycles that last less than 25 or greater than 30 days. Cycle length is more variable in teenage and older women than in women in their peak reproductive years.

The Menstrual Phase

The first day of menstruation marks the beginning of the menstrual cycle. Menstruation is triggered by the loss of progesterone support for the endometrium and results in the shedding of the upper layer of the endometrial lining. The endometrium consists of two layers called the stratum functionalis and the stratum basalis. It is the upper functionalis layer that is shed with each menstrual cycle and then regenerated anew in the next succeeding cycle. The shedding of the functionalis layer is regulated by ovarian steroid hormones. Fig. 2A and B show the pattern of reproductive hormone levels during the phases of the menstrual cycle in women. Regression of the corpus luteum during the late secretory phase leads to a sharp decline in progesterone and estradiol levels, initiating the process of tissue breakdown and menstruation in the endometrium. The onset of menstruation is an inflammatory response leading to the influx and activation of leukocytes and various immune cells including macrophages, natural killer cells, dendritic cells, and mast cells. These cells increase substantially in the endometrium during the late secretory phase of the cycle and make up as much as 40% of the cell population of the endometrium prior to menstruation. As progesterone levels decline sharply these cells are activated which triggers a cascade of matrix metalloproteinases (MMPs) that degrade the extracellular matrix

Fig. 2 Schematic outline of the ovarian events, endometrial and reproductive hormone level changes throughout the menstrual cycle. (A) New primary follicles are recruited, selected, and one becomes the dominant follicle destined to ovulate. Following ovulation the corpus luteum forms and produces progesterone during the secretory phase. Changes in the hormones estradiol, progesterone, follicle stimulating hormone (FSH) and luteinizing hormone (LH) are depicted. (B) The three phases of the menstrual cycle are indicated. Day 1 of the menstrual cycle is the first day of menses. Ovulation occurs at the end of the proliferative phase of the cycle.

and destabilize blood vessels in the endometrium. MMPs show increased expression and activity at menstruation when ovarian hormones are low. Of the MMP family, seven members are expressed in cell- and menstrual cycle-specific patterns in the uterus and their substrates include collagens, laminin, fibronectin, and other matrix proteins. Expression of inflammatory mediators in the endometrium such as interleukins and chemoattractant proteins is also increased. The sharp drop in circulating progesterone levels also causes vasoconstriction of the spiral arteries in the basal endometrium leading to local hypoxia and further tissue breakdown. This vasoconstriction occurs in response to the high levels of endothelins, potent vasoconstrictors, that show maximal activity at the end of the secretory phase. As these vessels constrict and then dilate they bleed and contribute further to the sloughing of the endometrium. Finally, the premenstrual fall in progesterone also leads to a decline in 15-hydroxyprostaglandin dehydrogenase activity, which increases the availability of prostaglandin $\text{PGF2}\alpha$, a potent stimulator of myometrial contractility, further facilitating the sloughing of the functionalis layer of the endometrium. Amazingly, the repeated cycles of inflammation and tissue breakdown during menstruation completely resolves without any residual scarring or loss of function. During this period of endometrial breakdown the levels of LH, FSH, estradiol, and progesterone are low due to low frequency and low amplitude pulses of

GnRH. However, by day 3, both FSH and LH levels begin to rise slowly and these increases in gonadotropins will stimulate growth of some of the ovarian follicles recruited during the late secretory phase. As the follicles grow in size they also achieve steroidogenic capacity and begin to secrete estradiol, so that estradiol levels also begin to rise by day 3 (Fig. 2).

The Proliferative Phase

The phase of the menstrual cycle leading up to ovulation is called the proliferative phase. Although the proliferative phase typically occupies the first half of the cycle, its length can vary. In ovulatory cycles of more or less than 28 days' duration, the deviation from the average is largely due to differences in the length of the follicular phase.

During the first 4–5 days of the proliferative phase, development of the recruited ovarian follicles continues. Due to the low levels of estradiol and progesterone both FSH and LH secretion increase. FSH induces granulosa cell proliferation and the recruited follicles build up several layers of granulosa cells. FSH also induces the enzyme aromatase in granulosa cells, increasing the amount of estradiol produced from androgens that diffuse from the theca cells to the granulosa cells. The proliferative phase of the cycle is characterized by a progressive increase in the synthesis and secretion of estradiol from the developing early antral follicles. FSH also induces expression of LH receptors on the granulosa cells making them LH responsive. By days 5–7 of the cycle, a single follicle predominates which will mature and ovulate between days 13 and 15. The remaining recruited follicles will undergo atresia. The process by which one follicle from a group of recruited follicles is selected to become the dominant follicle destined to ovulate is not well understood, but is thought to involve androgens. During the mid- to late proliferative phase, the rising estradiol levels in the circulation suppress FSH secretion, thereby preventing new follicular recruitment. The rising estradiol also leads to more LH secretion by the pituitary as well as increased ovarian responsiveness to LH. The increasing estrogen levels also cause growth of the endometrial tissue lining the uterus. These visible changes in the endometrium are defined as the "proliferative phase."

The uterine endometrium is a primary target organ of estradiol. During the proliferative phase the uterine endometrium begins to thicken and the uterine glands enlarge. The increase in thickness of the endometrium can be measured by ultrasound. The uterine epithelial cells on the surface of the lumen and lining the glands proliferate in response to rising estrogen. The glands proliferate and elongate deep into the stroma of the endometrial basalis. Immediately prior to ovulation, the glands are maximally elongated and markedly coiled. The supply of blood vessels in the endometrium is also markedly increased due to proliferation of the spiral arteries that grow upwards from the basal layer into the functionalis layer of the endometrium.

By days 10–13 of the proliferative phase the antral follicle(s) reaches peak size and estradiol levels also continue to rise to reach their maximum levels by day 12 or 13. This sustained rise in estradiol activates positive feedback at the level of the hypothalamus (through kisspeptin) and also directly at the pituitary to increase LH secretion. Approximately 24–48 h after the peak in estradiol, an LH surge occurs characterized by a marked, rapid increase in frequency and amplitude of LH pulses. Ovulation occurs about 9–12 h after the peak of the LH surge accompanied by a smaller FSH surge. The LH surge initiates the resumption of meiosis in the oocyte within the largest antral follicle and extrusion of the mature ovum through the follicle wall.

The Luteal Phase

The length of the luteal phase in women is normally approximately 14 ± 2 days. The corpus luteum forms from the follicle after ovulation and its production of progesterone becomes the dominant feature of the luteal phase. The corpus luteum in humans is also made up of large and small luteal cells that produce estrogen and inhibin, as well as progesterone and 17-hydroxyprogesterone. These hormones are all produced in quantities that are measureable in the peripheral circulation.

The high concentrations of progesterone present during the luteal phase exert a marked negative feedback effect on both FSH and LH secretion in spite of the moderate levels of estradiol being produced by the corpus luteum at this time. These negative feedback effects occur at the level of the hypothalamus with progesterone causing a significant inhibition in the frequency of GnRH pulses, resulting in only baseline FSH and LH secretion. The corpus luteum is dependent on these basal levels of LH for its ability to produce progesterone. If pregnancy does not ensue, the corpus luteum will spontaneously regress due to apoptosis of the luteal cells. When progesterone, estradiol and inhibin levels begin to decline at the end of the luteal phase, secretion of GnRH is no longer inhibited and a new cycle of follicular development is initiated. FSH secretion will begin to rise in response to the drop in hormone production by the corpus luteum and a new crop of follicles will be recruited for the next cycle. If a conceptus is present, the corpus luteum will not undergo regression but will be maintained due to the production of human chorionic gonadotropin (hCG) by the trophoblast cells of the early embryo. hCG is a glycoprotein hormone that is homologous to LH and can bind to LH receptors in the corpus luteum with an affinity similar to LH. hCG is critical for maintenance of the corpus luteum and continued progesterone secretion. The corpus luteum of pregnancy will continue to be maintained and secrete progesterone until the fetal placenta assumes this role near the end of the first trimester of pregnancy.

Progesterone is the dominant hormone during the secretory phase and promotes endometrial maturation so that implantation can occur. During the luteal phase the endometrial glands become fully differentiated and secrete the nutrients that will be needed by an implanting embryo. The endometrium is thick and spongy, due to increased vascularity and maturation of the spiral arterioles. There is also a marked influx of leukocytes and the endometrial stromal cells undergo a unique process known as decidualization. The stromal cells enlarge and acquire a foamy appearance indicative of increased metabolism, glycogen and lipid accumulation, and synthetic capacity. The cells change in appearance from fibroblast-like cells to large round cells with an abundant

cytoplasm and become terminally differentiated. Decidualization of the endometrium is first initiated in the stromal cells located around the elongated and coiled spiral arteries and then spreads under and around the glands by the mid- to late luteal phase (around 10 days after ovulation). The presence of decidual cells and the influx of leukocytes leads to an increase in cytokines and chemokines within the endometrium as well as hormones such as prolactin and insulin-like growth factor binding protein 1. If implantation does not occur, the corpus luteum will regress, leading to a drop in progesterone production and the endometrium will undergo ischemic necrosis leading to menstruation. If pregnancy does occur, the lifespan of the corpus luteum will be extended by hCG prolonging progesterone secretion and decidualization of the stroma will continue.

In spite of some fundamental differences between the estrous cycle of domestic mammals and the menstrual cycle of primates and women, many of the physiologic mechanisms are comparable between all these species.

Introduction

In female mammals, reproductive processes such as puberty, ovarian cyclicity and pregnancy require precise coordination of the hypothalamic–pituitary–ovarian (HPO) axis. The major components of the HPO axis include the hypothalamic gonadotropin-releasing hormone (GnRH) neurons, the pituitary gonadotropes and ovarian structures, such as follicles and the corpus luteum (Fig. 1). The gonadotropes respond to GnRH by releasing the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn stimulate folliculogenesis and steroid and peptidergic hormone secretion by the ovaries. The hypothalamic, pituitary, and ovarian hormones integrate to orchestrate the different events within the reproductive cycle so they occur in a timely manner to ensure successful reproduction (see earlier review (Beshay and Carr, 2013)). In this chapter, we present an overview of the key components and hormones of the HPO axis, discuss the complex endocrine interactions that exist between the different levels of this axis, and summarize recent findings on the main factors and mechanisms that regulate the HPO axis in the female mammals.

The Hypothalamus

The hypothalamus encompasses the lower part of the lateral wall and the floor of the third ventricle, containing several localized clusters of neurons, called nucleus, that control multiple processes such as metabolism, reproduction, and behavior. The median eminence located at the base of the hypothalamus extends to the pituitary and contains neurosecretory neurons that control hormone synthesis and secretion from the pituitary.

Fig. 1 Schematic showing the components of the hypothalamic–pituitary–ovarian axis.

GnRH and Its Mode of Release

The GnRH neuron

The decapeptide, GnRH—the primary hypothalamic regulator of reproductive function, is synthesized in specialized neurons as part of a larger precursor molecule (prohormone) containing 92 amino acids. GnRH neurons originate in the olfactory placode and migrate to the hypothalamus where several hundreds of these cells can be found diffusely distributed in the anterior portion of the hypothalamus, the preoptic area (POA), and more caudally in the medial basal hypothalamus (MBH). Most GnRH neurons have two dendritic projections, which may extend remarkable distances (2–3 mm) from the cell body. The main target of hypothalamic GnRH projections is the primary plexus of the pituitary portal system in the median eminence.

The hypothalamic–pituitary portal vasculature

Upon reaching the median eminence, GnRH axons end on capillary loops that give rise to long portal veins that descend along the pituitary stalk to terminate in the pituitary sinusoids. The portal system facilitates the rapid exchange between the hypothalamus and the pituitary, requiring only minute amounts of neurohormones to stimulate release of hormones by the pituitary. The superior hypophyseal arteries form the primary capillary plexus that supplies blood to the median eminence. From this capillary system, the blood is drained in hypophyseal portal veins to the secondary plexus, a network of fenestrated sinusoid capillaries that provide blood to the anterior portion of the pituitary. This anatomical arrangement allows rapid and undiluted transport of GnRH to the pituitary gland.

GnRH biosynthesis

To date, three isoforms of GnRH (GnRH-I, GnRH-II, and GnRH-III) have been identified in humans and many others have been detected in fish, amphibians, and protochordates. GnRH-I is the classic hypothalamic peptide responsible for regulating the synthesis and secretion of gonadotropins. GnRH-II, first reported in brain tissue and since been found in other peripheral tissues, such as the uterus and ovaries is also capable of stimulating LH release. The role of GnRH-III, first identified in the lamprey, in humans remains unclear (Schneider et al., 2006).

Upon synthesis, GnRH-I gets transported to the median eminence of the hypothalamus and then released in the portal circulation in a pulsatile manner. The lifespan of GnRH-I is very short with a half-life of 2–4 min. Because of its short half-life and rapid dilution in the peripheral circulation, GnRH-I concentrations are very difficult to measure in the peripheral circulation.

GnRH pulsatility

The cellular network that elicits the pulsatile increases in GnRH secretion is referred to as the “GnRH pulse generator” and includes the synchronously firing GnRH neurons. While there is supporting evidence that GnRH pulsatility is intrinsic to GnRH neurons themselves and that extensive intercellular mechanisms orchestrate synchrony within the network, more recent observations strongly indicate that other neurons in the MBH target the GnRH neuronal network directly to drive the pulsatile release of GnRH (Fig. 2). Kisspeptin, the most potent stimulator of GnRH secretion yet discovered, appears to be an integral component of the GnRH pulse generator. Of particular interest are the neurons in the arcuate nucleus (ARC) that co-express the neuropeptides kisspeptin, neurokinin B, and dynorphin, termed KNDy neurons. In contrast to the endogenous opioid dynorphin that has inhibitory actions on GnRH release, neurokinin B is generally stimulatory to GnRH secretion. Based on the action of these neuropeptides on GnRH release and the neuroanatomical evidences that KNDy neurons communicate with GnRH neurons (particularly at the level of the median eminence), a model for GnRH pulse generation has been established. This

Fig. 2 Schematic depicting the control of the GnRH neurons in the hypothalamus. KNDy neurons in the arcuate nucleus project to GnRH cell bodies and axonal projections to modulate GnRH release into the median eminence (ME).

model proposes that GnRH pulse generation is initiated in the KNDy neuronal network in the ARC by a reciprocating interplay of stimulatory neurokinin B signals and inhibitory dynorphin inputs and the output of the pulse generator is relayed to GnRH neurons via the release of kisspeptin from axonal terminals originating from KNDy neurons (Fig. 2; Lehman et al., 2010).

The Pituitary Gland

The pituitary, also known as the master endocrine gland, is a small gland located beneath the third ventricle of the brain and above the sphenoidal sinus in a bone cavity called sella turcica. The pituitary gland contains two major lobes: anterior and posterior.

The Anterior Pituitary

Development

The anterior pituitary, also known as adenohypophysis, is a classic endocrine gland in that it is composed of secretory cells of epithelial origin supported by connective tissue rich in blood and lymphatic capillaries. The anterior pituitary is derived from the ectoderm, more specifically from the Rathke's pouch, part of the developing hard palate in the fetus. The Rathke's pouch eventually loses its connection with the pharynx, giving rise to the anterior pituitary. The pouch becomes committed to organ development several days prior to the expression of markers of individual cell types within the mature anterior pituitary gland. Between the time of organ commitment and maturation, a series of cell type-specific differentiation and proliferative events occur.

Cell types

The five cell types present in the mature anterior pituitary gland are defined based on the trophic factors that they synthesize and secrete. Corticotropes secrete adrenocorticotrophin, thyrotropes produce thyroid-stimulating hormone, somatotropes secrete growth hormone, lactotropes produce prolactin and gonadotropes secrete the gonadotropins, LH and FSH.

The Posterior Pituitary

The posterior pituitary, also known as neurohypophysis, is a grouping of axonal projections that secretes oxytocin responsible for increasing uterine contractions and vasopressin, an antidiuretic hormone.

Gonadotropes

Gonadotropes are specialized basophilic cells in the anterior pituitary that express cell surface receptors for GnRH and produce LH and FSH.

The GnRH receptor

The GnRH-I receptor is a G-protein coupled receptor that utilizes inositol triphosphate and diacylglycerol as second messenger molecules to stimulate protein kinase, release calcium ions, and cyclic adenosine monophosphate activity. While the pituitary is the classic target tissue for GnRH actions, the GnRH-I receptor is expressed in many other tissues, including ovarian follicles, pancreas, liver, heart, and the placenta. Importantly, the continuous activation of the GnRH receptor results in its desensitization thus enabling the use of GnRH agonists for treatment of reproductive disorders such as precocious puberty and endometriosis, and to prevent GnRH actions prior to ovarian stimulation cycles for in vitro fertilization. Therefore, only pulsatile GnRH administration can restore normal gonadotropin secretion in individuals lacking endogenous GnRH secretion (e.g., Kallmann syndrome).

Luteinizing hormone

LH is a glycoprotein heterodimer consisting of two subunits: α - and β -subunits. The α -subunit is common between LH, FSH, and TSH and consists of 92 amino acids. The β -subunit is distinct and hormone-specific, which allows the different biological actions of each hormone. The LH β -subunit has 120 amino acids and one to two sialic acid residues, giving it its shorter half-life of approximately 20 min. LH is secreted in a pulsatile manner except preceding ovulation when a massive release of LH (LH surge) occurs to trigger ovulation. Since LH secretion is primarily regulated by GnRH, peripheral levels of LH serve as good surrogate markers for assessing pattern of GnRH release.

Follicle-stimulating hormone

FSH is also a glycoprotein heterodimer consisting of two subunits: α - and β -subunits. The FSH β -subunit contains 118 amino acids and 5 sialic acid residues. The sialic acid content of FSH and LH is responsible for the half-life of these hormones, with greater number of sialic acid residues yielding longer half-life. FSH has a half-life of approximately 3–4 h, thus providing sustained support to facilitate growth of ovarian follicles.

Ovaries

The ovaries are the female gonads and are primarily responsible for the generation of gametes and production of hormones that regulate reproductive function. In most mammals, a pair of ovaries is present on either side of the body and is structurally

made of inner medulla and the outer cortex that is encapsulated by a connective tissue rich membrane called tunica albuginea. While the medulla contains vascular structures such as blood and lymphatic vessels, the cortex contains the follicles, which are the functional units of the ovary.

Follicular Development

An ovarian follicle contains the female gamete—oocyte, and the somatic cells, granulosa and theca cells. The number and type of somatic cells varies depending on the stage of follicular development. During the embryonic development, the primordial germ cells (PGCs) originate from the endoderm of the yolk sac and migrate into the genital ridge. These PGCs mitotically divide to form the oogonia, which later undergoes meiosis to form the oocyte. The primordial follicles are formed when the naked oocytes are surrounded by the pregranulosa cells (Fig. 3). These primordial follicles form the ovarian follicular pool or reserve and majority of these follicles remain in a quiescent state. A few follicles emerge from the reserve at specific intervals, a process termed as activation, and either undergo atresia (degeneration) or develop into primary follicles with the transformation of granulosa cells from spindle to cuboidal shaped. Follicular growth continues with granulosa cells dividing to form several layers around the oocyte leading to the development of the preantral follicle. During this developmental period, the follicle also acquires the theca cells that surround the granulosa cells. It has been suggested that follicular development up until the preantral stage occurs in a gonadotropin-independent manner, however, the role of gonadotropins cannot be ruled out because FSH receptors are present in early follicular stages.

Subsequent follicular differentiation occurs under the influence of gonadotropins with preantral follicles progressing to the antral stage with development of a fluid-filled cavity, termed the antrum. Selection of a dominant follicle from the antral follicular pool that is destined for ovulation (Fig. 3) occurs under the influence of FSH. Further maturation into Graafian or preovulatory follicle occurs predominantly under LH stimulation. Upon ovulation, the release of egg from the follicle, subsequent transformation of the follicular remnant into the endocrine structure corpus luteum is driven by LH.

Ovarian Hormones

The ovarian hormones produced under the influence of LH and FSH include steroidal and non-steroidal polypeptide hormones. Androgens and estrogens are produced by theca and granulosa cells, respectively. Under the influence of LH, theca cells take up cholesterol and convert it into 17-hydroxy-pregnenolone through the Δ^5 pathway, which is then acted on by 17-hydroxylase to synthesize the androgen androstenedione. Majority of androstenedione is aromatized into the major estrogen, estradiol, by the enzyme aromatase (CYP19) in granulosa cells, a process that occurs under the influence of FSH. In the corpus luteum, synthesis of progesterone is stimulated by LH through the Δ^4 pathway (Miller, 2008).

The non-steroidal hormones, among others, include those belonging to the transforming growth factor beta (TGF β) family namely inhibin, activin, anti-Mullerian hormone (AMH), TGF α , bone morphogenetic proteins, and growth differentiation factors. Other factors produced by the ovary include insulin-like growth factors (IGF), kit ligand, fibroblast growth factors, epidermal growth factors, and prostaglandins.

Inhibins

Inhibins are protein hormones consisting of two subunits α and β and are secreted mainly by the granulosa cells under the influence of FSH but are also produced by the pituitary gonadotropes. Two forms of inhibin have been identified, Inhibin-A and -B. The α subunits are identical, while the β -subunit differs between both forms of inhibin (denoted as β_A and β_B , respectively). Inhibin-B is predominantly secreted during the follicular phase, while the A form is secreted during the luteal phase. Inhibins function to suppress FSH secretion by the anterior pituitary.

Activins

Activins are secreted by granulosa cells and are homo- or hetero-dimers of the inhibin β subunits, with activin A and B being the homodimer of two β_A and β_B subunits, respectively and AB being the heterodimer. Activin is also produced in the pituitary and

Fig. 3 Schematic representation of the different stages in the ovarian follicular development.

stimulates FSH release. Other β forms have been identified, raising the possibility of additional homo- and hetero-dimeric forms although their role in regulation of gonadotropin secretion is still being ascertained (Wijayarathna and De Kretser, 2016).

Follistatin

Follistatin is a monomeric glycoprotein produced by the ovary as well as anterior pituitary folliculostellate cells. It is a high affinity activin binding protein therefore its main role in female reproduction is to sequester activin and inhibit FSH secretion.

Anti-Müllerian hormone

AMH is produced by granulosa cells. AMH production increases from primordial to preantral follicle stage, being highest in preantral and small antral follicles but declining thereafter. AMH is implicated in inhibition of follicular recruitment from the resting pool. It acts on antral follicles to decrease FSH sensitivity, reduce aromatase activity and allow the selection of the dominant follicle (Visser and Themmen, 2014). AMH is increasingly being used as a biomarker of the relative size of the ovarian reserve (Pankhurst, 2017). Recently, receptors for AMH have also been identified in the mouse and human hypothalamic neurons suggesting a potential direct role in the neuroendocrine system (Cimino et al., 2016).

All intra-ovarian factors act in a paracrine manner to influence follicular growth and maturation (Gougeon, 2010).

Regulation of the HPO Axis

The cyclic functioning of the HPO axis involves a complex interaction between the hypothalamus, pituitary and ovary that include feed-forward, feedback and paracrine loops (Fig. 4).

Fig. 4 Hypothalamic–pituitary–ovarian axis depicting feed-forward, feedback, and paracrine loops.

The Feed-Forward Regulation in HPO Axis

A pulsatile release of GnRH by the hypothalamic GnRH pulse generator leads to feed-forward regulation of the anterior pituitary gonadotropes that promotes synthesis, storage and secretion of gonadotropins (Fig. 4). Gonadotropin secretion depends on the frequency of pulsatile GnRH secretion with faster frequency favoring LH- β subunit gene transcription and LH release, and slower frequency favoring FSH- β gene transcription and FSH release.

The gonadotropins released under the influence of GnRH have feed-forward actions at the ovarian level (Fig. 4) where they bring about morphological and hormonal changes. These include regulation of follicular differentiation by FSH, induction of ovulation and formation of corpus luteum by the surge release of LH, stimulation of theca cell androgen production by LH, conversion of androgen to estrogen as well as synthesis of inhibin and activin by FSH, and the stimulation of progesterone production in the corpus luteum by LH.

The Feedback Regulation of the HPO Axis

The feedback regulation of HPO axis, which may be negative or positive, involves control of hormonal release from the hypothalamus, pituitary or ovary by the end products of their stimulation (Fig. 4). Such feedback ensures that follicular growth, maturation, ovulation, corpus luteum formation and preparation of the uterine lining occur in a controlled and timely manner so as to facilitate successful conception or renewal of the reproductive cycle in the event of unsuccessful conception.

Negative feedback regulation

Estradiol, progesterone, and inhibin are the main ovarian hormones that participate in the negative feedback regulation of the neuroendocrine axis to decrease gonadotropin release (Fig. 4). At the level of the hypothalamus, the exact afferent neuronal pathways and mechanisms mediating the gonadal steroid-dependent negative feedback process remain unresolved as the majority of GnRH neurons do not express receptors for gonadal steroids. Current evidence suggests that kisspeptin neurons located in the POA and ARC play a key role conveying the feedback regulatory effects of gonadal steroids on GnRH neurosecretory activity. Kisspeptin neurons located in the ARC (KNDy neurons) express receptors for gonadal steroids and have been postulated to mediate the negative feedback actions of estradiol on GnRH secretion (Lehman et al., 2010). There is considerable evidence that the inhibitory effects of progesterone on GnRH pulsatile secretion is mediated through dynorphin from KNDy neurons. This premise is supported by the observations that KNDy neurons express the progesterone receptor, local administration of an antagonist to the dynorphin receptor in the MBH increases LH pulse frequency during the luteal phase in sheep, ovariectomy decreases the expression of dynorphin in the ARC and local administration of a progesterone receptor antagonist to the ARC disrupts the negative feedback actions of progesterone on GnRH/LH secretion (Lehman et al., 2010).

The inhibitory effects of estradiol on gonadotropin secretion, apart from its action on GnRH release, also appear to be partially mediated via direct pituitary effects. This involves repression of FSH- β subunit expression by estradiol. Inhibin from the ovary also exerts negative feedback on the pituitary FSH secretion and one mechanism proposed involves competing with activin in binding to its receptors, thereby preventing activin's role in stimulating FSH secretion.

Positive feedback regulation

The ovarian hormone estradiol is the main player that exerts positive feedback action in the HPO axis (Fig. 4) and research findings suggest that there are important differences in the neuronal systems mediating its positive actions on GnRH surge release between different animal models. While in rodents it appears that the anteroventral periventricular area is the main hypothalamic area involved, in sheep and primates the estradiol positive feedback is largely mediated in the MBH. Despite these differences, in most female mammals increased expression of kisspeptin during the late follicular phase promotes a robust release of GnRH that in turn stimulates the surge release of gonadotropins. In humans, the anterior pituitary appears to be an important site of estradiol positive feedback regulation of LH secretion.

Paracrine Regulation

In addition to the positive and negative feedback regulation discussed earlier, there are several paracrine/autocrine regulatory loops at all levels of the HPO axis. For instance, GnRH has been shown to regulate its own secretion (Padmanabhan et al., 1995). Several neuropeptides produced by hypothalamic neurons, such as kisspeptin, also participate in paracrine regulation of GnRH release. More recent studies suggest neurosteroids produced within the hypothalamus may also participate in feedback regulation of GnRH release (Kenealy et al., 2013). At the pituitary level, activin, inhibin and follistatin produced by the pituitary modulate FSH synthesis through paracrine actions. Activins promote FSH secretion by increasing the number of GnRH receptors on gonadotropes (Fortin et al., 2015) while inhibin and follistatin oppose activin actions.

At the level of the ovary, there are several paracrine systems operational. Some examples of such paracrine regulation include: (1) modulation of activin action by its binding protein, follistatin, (2) promotion of theca androgen production by inhibin, (3) down-regulation of FSH receptors in antral follicles by AMH, which helps reduce FSH sensitivity thus allowing emergence of dominant follicles, (4) induction of inhibin and gonadotropin receptors by estradiol, and (5) promotion of FSH-induced estrogen production in granulosa cells and LH-induced androgen production in theca cells by inhibins. Another important example of a paracrine

Fig. 5 Hypothalamic, pituitary, and ovarian hormonal, ovarian follicular and corpus luteum and uterine epithelial changes during the menstrual cycle. The mean concentrations of each of the hormonal changes are shown with LH pulsatile secretion shown as insets during the early and later follicular, periovulatory and luteal phases. *E2*, estradiol; *P4*, progesterone; *inh.A*, inhibin A; *inh.B*, inhibin B. feedback loop within the ovary involves androgen and inhibin with inhibin acting on theca cells to regulate androgen production and androgen acting back on granulosa cells to regulate inhibin production.

Other Regulators of HPO Axis

In addition to regulation of the HPO axis by its components and their secretions, nutrition, metabolic status and seasonality, among other factors, also regulate the HPO axis. Reproductive processes in female mammals can be energetically costly, thus requiring a coordinated regulation by the nutritional and metabolic systems. Therefore, the HPO axis must receive and integrate information about peripheral metabolic cues in order to regulate reproductive function. Neuropeptides and leptin are the major cues of the body's metabolic status.

Although leptin, a metabolic hormone produced primarily by adipocytes, does not affect GnRH secretion directly as its receptor is not present on GnRH neurons, the effects of leptin are mediated through intermediate neuronal pathways that encompass hypothalamic neuropeptide Y (NPY)/agouti-related protein (AgRP) neurons and proopiomelanocortin (POMC) neurons. While NPY has inhibitory action, melanocyte-stimulating hormone alpha (α MSH), one of the products of the POMC gene, has stimulatory effect on GnRH neurons (Evans and Anderson, 2017). Undernutrition upregulates NPY expression in the ARC reducing the GnRH pulsatility while increased leptin concentrations in circulation not only downregulates NPY but also increases α MSH increasing the GnRH/LH pulsatility (Evans and Anderson, 2017).

Photoperiod is a major factor determining annual changes in reproductive function in mammalian species that breed seasonally such as sheep (short day breeders) and mares (long day breeders). While the neuronal mechanisms involved in photoperiod control of GnRH/LH pulses remain uncertain it may involve hypothalamic dopaminergic neurons, KNDy neurons in the ARC, and neurons expressing RF-amide related peptide 3, which is also referred to gonadotropin inhibitory hormone 3 (Clarke, 2011). Another important factor modulating GnRH release in female mammals is stress. Stress influences the GnRH pulse generator reducing the frequency of GnRH/LH pulses through increased cortisol secretion (Whirledge and Cidlowski, 2010).

Apart from actions at the GnRH neurons, metabolic hormones such as insulin, leptin and adiponectin enhance gonadotropin synthesis and release via direct action on the gonadotropes. Stress in addition to reducing GnRH pulsatility also reduces pituitary responsiveness to GnRH, and amplifies the negative feedback while inhibiting the positive feedback effects of estradiol (Whirledge and Cidlowski, 2010).

At the level of the ovary, the major metabolic hormones modulating ovarian function are insulin and adiponectin. Insulin is referred to as a co-gonadotropin in the ovary as in addition to acting alone can potentiate gonadotropin action. Insulin can also activate IGF receptors in the ovary. The ovary also expresses adiponectin receptors and adiponectin promotes ovulatory and luteinization processes induced by the LH surge by increasing steroidogenesis, prostaglandin synthesis and angiogenesis (Palin et al., 2012). While glucocorticoids have an anti-inflammatory role in the ovary and aid in the formation of the corpus luteum, stress-induced increase in glucocorticoids has negative effects by suppressing the LH-induced steroidogenesis (Whirledge and Cidlowski, 2010).

Conclusions

Precise coordination of components of the HPO axis via endocrine and paracrine feedback mechanisms is essential to maintain adequate reproductive cyclic function. At the beginning of reproductive cycle, increasing levels of LH and FSH facilitate growth of multiple follicles to early antral stage (Fig. 5). The estradiol and inhibin B produced by the growing follicles exert negative feedback effects at the hypothalamic–pituitary level leading to a reduction in FSH secretion. The increased estradiol also promotes uterine epithelial growth to prepare for receiving the conceptus. The follicle that develops increased sensitivity to FSH in the face of reduced FSH support differentiates into the dominant follicle. The dominant follicle contributes to a further increase in estradiol secretion leading to positive feedback response at the hypothalamic–pituitary level and surge release of gonadotropins triggering ovulation. Upon release of the oocyte, the follicle remnant develops into a progesterone and inhibin A producing organ called corpus luteum. The increase in progesterone and inhibin secreted by the corpus luteum exerts negative feedback at the hypothalamic–pituitary level to reduce LH and FSH secretion. In the event of conception, luteal function is maintained by factors produced by the developing conceptus. If conception fails, the corpus luteum undergoes regression leading to a decline in progesterone and inhibin A secretion that result in removal of negative feedback effects at the hypothalamic–pituitary level leading to an increase in LH and FSH secretion and reinitiation of the cycle. All in all, the HPO axis integrates peripheral signals and via feed-forward, feed-back and paracrine mechanisms it enables reproductive success to ensure the survival of the species.

Glossary

Activating mutation A modification in DNA sequence that confers gain of function phenotype.

Activin A gonadal peptide that promotes FSH production from pituitary.

Adipocyte The major cell type in the fat or adipose tissue.

Anovulatory A failure to ovulate or produce eggs.

Antral follicle A mature follicle in the ovary that consists of an antrum.

Atrophy A tissue/cell that shows degeneration.

Autocrine A hormone or a chemical messenger produced from and acting on the same cell.

Blocking antibody An antibody that prevents the binding of a ligand to its binding partner and blocks its actions.

Chorionic gonadotropin A glycoprotein hormone produced by trophoblast cells in placenta.

Corpus luteum A steroidogenic structure formed after the egg is released from a fully grown ovarian follicle.

Counter current chromatography A classical separation technique that allows distribution of different proteins into different solvent phases.

Ectopic expression Expression from tissues other than the original tissue of expression.

Endothelial cell A cell that lines the inner surface of blood and lymphatic vessels.

Enzyme linked immunosorbent assay A technique that measures the concentration of antigens by using enzyme linked antibodies as detection reagents. Commonly abbreviated as ELISA.

Equine Horse or its family member.

Estrogen A female steroid mostly produced from ovarian granulosa cells.

Expression vector A synthetically designed plasmid or virus-based carrier to express genes in cells.

Follicular atresia Breakdown of follicles within an ovary.

Folliculogenesis Formation of new follicles.

Follistatin A gonadal peptide that antagonizes activin actions in many cells.

Gonadectomy Removal of gonads, usually by surgical methods.

Gonadotrope A pituitary cell that produces gonadotropins LH and FSH.

Gonadotropin-releasing hormone A 10-amino acid peptide hormone released from hypothalamus in the brain and binds to gonadotropes to regulate gonadotropin secretion from pituitary.

Granulosa cell A cell that is the functional unit of a ovarian follicle.

Homologous hormones Hormones from the same species.

Hyperandrogenemia A condition in which androgen is in excess.

Hyperplasia A condition in which there is an increase in cell proliferation leading to tissue enlargement.

Hypogonadism A condition that manifests in small gonads with reduced function.

Hypophysectomy Surgical removal of the pituitary.

Hypoplastic Incomplete development of a tissue that consists of less number of cells.

Hypothalamus A tiny structure at the base of the brain that controls the pituitary and other organs in the body.

Immunoneutralization Blocking the hormone action by specific antibodies.

In vitro Outside the biological context, usually culturing and treating cells in a petri dish.

In vivo Inside a living organism or whole animal.

Inactivating mutation A modification in DNA sequence that confers loss of function phenotype.

Inhibin A gonadal peptide that inhibits FSH production from pituitary.

Lactotrope A pituitary cell type that produces prolactin hormone.

Leydig cell The predominant cell type within the testis interstitium, produces testosterone.

Macro-heterogeneity Glycoforms that have differences in the number of N-linked glycans.

Micro-heterogeneity Refers to glycoforms that have differences in terminal sugars of N-glycan chains.

Mutagenesis Method to introduce mutations into DNA.

Osteoclast A cell type in the bone that destroys bone.

Ovarian senescence A condition in which ovary ceases to produce eggs.

Ovariectomy Surgical removal of the ovary.

Paracrine A hormone secreted by one cell acting on a neighboring cell within a tissue.

Perfusion Culturing cells in a solution phase and testing the effects of drugs on them.

Pituitary An endocrine gland closely connected with the hypothalamus and consists of multiple hormone-producing cell types.

Placenta An organ that connects fetus to the uterus and facilitates exchange of nutrients and other components via maternal blood circulation. Placenta also produces hCG during pregnancy.

Polarized cell A cell that has distinct compartments called apical and basolateral and also exhibits electrical differences along the cell membrane.

Pre-ovulatory follicle A fully grown follicle from which oocyte is released.

Progesterone A female steroid hormone produced from the corpus luteum.

Radioimmunoassay A radioactive technique that is used to measure hormones.

Radioreceptor binding assay A radioactive technique that is used to measure the binding characteristics of a hormone to its receptor.

Sedimentation The settling of particles from a liquid upon centrifugation.

Seminal vesicle An accessory male sex gland whose secreted fluids combine with sperm.

Sertoli cell A somatic nurse cell that maintains germ cells in the seminiferous tubules of testis.

Spermatid An advanced stage male germ cell that ultimately gives rise to sperm.

Spermatogenesis A process that occurs in the testis and produces sperm.

Targeted expression Expression of a foreign gene in the same cell type as the endogenous cell using cell-specific promoters.

Testosterone A male steroid produced from Leydig cells in the testis.

Theca cell A cell located outside the follicle that produces testosterone in response to LH.

Thyrotrope A pituitary cell type that produces thyroid stimulating hormone.

Transgene A natural or genetically modified gene transferred from one species to another.

3'-Untranslated region A region at the 3'-end of a gene that is transcribed but not translated, usually plays a role in stability of mRNA, commonly designated as 3'-UTR.

Abbreviations

cDNA	Complementary DNA
CGA	Common gonadotropin α -subunit
CTP	Carboxy terminal peptide
DNA	Deoxy ribonucleic acid
ELISA	Enzyme-linked immunosorbent assay
FSH	Follicle-stimulating hormone
FSHR	FSH receptor
GnRH	Gonadotropin-releasing hormone
hCG	Human chorionic gonadotropin
hpg	Hypogonadal
LH	Luteinizing hormone
LHR	Luteinizing hormone receptor
MDCK	Madin-Darby canine kidney
miRNA	Micro-RNA
mRNA	Messenger RNA
RIA	Radio immunoassay
RNA	Ribonucleic acid
TSH	Thyroid-stimulating hormone

Introduction

Gonadotropins are glycoprotein hormones produced by gonadotropes in the anterior pituitary, an endocrine gland located beneath the hypothalamus of the brain. Their existence was identified nearly 100 years ago by hypophysectomy, a surgical procedure in which the pituitary gland is excised, that resulted in gonadal atrophy. Subsequently, they were biochemically purified from pituitary glands of a number of vertebrate species including post-mortem humans. Gonadotropes produce two

Table 1 A summary of different gonadotropins

<i>Hormone</i>	<i>Subunits</i>	<i>Tissue</i>	<i>Source</i>
Luteinizing hormone (LH)	$\alpha + \text{LH}\beta$	Pituitary	Gonadotrope
Follicle-stimulating hormone (FSH)	$\alpha + \text{FSH}\beta$	Pituitary	Gonadotrope
Chorionic gonadotropin (CG)	$\alpha + \text{CG}\beta$	Placenta	Trophoblast
Pregnant mare serum gonadotropin (PMSG) ^a	$\alpha + \text{eCG}\beta$	Endometrial cups	Serum
Equine chorionic gonadotropin (eCG) ^a	$\alpha + \text{eCG}\beta$	Placenta	Chorion

^aPMSG and eCG are the same.

gonadotropins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH), named for their actions on ovaries, although they both act on testes as well (Table 1). During pregnancy, another gonadotropin is secreted in high levels from placental syncytio-trophoblast cells into urine. This is called chorionic gonadotropin (CG), also known as the pregnancy hormone. CG is also produced by pregnant mare, donkey and zebra placentas.

Gonadotropin Structure and Biosynthesis

Early biochemical studies using classical techniques such as counter current chromatography and sedimentation under denaturing conditions indicated that gonadotropins were heterodimers consisting of an α -subunit and a β -subunit. The subunits are non-covalently associated with each other and are easily separable. Meticulous manual protein sequencing techniques were used to discern amino acid sequences of individual gonadotropin subunits. These studies revealed that within a given species, the α -subunit was common between the gonadotropins. The α -subunit is also present in thyrotropin (thyroid-stimulating hormone or TSH) produced by thyrotropes, a distinct cell population in the pituitary. Significant protein sequence homology also exists between the gonadotropin subunits and across species. The non-covalent nature of the subunits allowed cross-species subunit reconstitution experiments such that inter-species hybrid heterodimers were assembled in test tubes. Depending on the species, the molecular weight of pituitary gonadotropin heterodimers range from 28 to 35 kDa. The critical amino acids that confer inter-subunit interaction, subunit assembly and antigenicity in gonadotropins were identified by various protein modification reagents. However, these studies were limited by unstable nature of the modified subunits and problems with subunit assembly often leading to biological inactivity of the resultant heterodimeric hormones.

One key feature identified by various protein modification and sequencing techniques was the presence of carbohydrate moieties covalently attached to Asn residues in both subunits of LH and FSH. N-glycosylation, the process by which sugars are assembled onto Asn residues, is a co-translational event that occurs early in the gonadotropin subunit synthesis in the rough endoplasmic reticulum. In the case of CG beta subunits, sugars are also attached onto Ser/Thr amino acid residues in the carboxy terminus ends. These O-linked sugars contribute to the longer half-life of hCG in circulation. Variations in terminal sugars are known to contribute to micro-heterogeneity observed in general in all glycoproteins, including gonadotropins. Recent studies also indicate that macro-heterogeneity due to lack of an entire sugar chain attached to one or two of the Asn residues is found in human FSH β -subunit. Using a variety of techniques to bulk produce pure hormones and biophysical and computational approaches, crystal structures of FSH and hCG have been solved and found to contain a characteristic cystine knot. These data gave clues about the 3-dimensional architecture of the hormone subunits, molecular basis of their physical interaction between the subunits and how carbohydrates are positioned on the dimer.

Gonadotropin Secretion and Action

Gonadotropin subunits must assemble within the gonadotropes and only FSH and LH heterodimers are secreted and detected in blood. In the case of human CG, free α - or β -subunits are ectopically expressed under some pathological conditions. Gonadotropin secretion is under tight physiological control involving feed-forward and -feedback endocrine regulatory loops. The hypothalamus-derived gonadotropin releasing hormone (GnRH) is the main activator of gonadotropin secretion. Sex steroids and gonad-derived peptides known as inhibins and follistatin act as negative regulators of FSH secretion. Another related peptide, activin, also identified originally in gonadal extracts, positively regulates FSH secretion. Activins, inhibins and follistatin are also locally expressed within the pituitary and regulate FSH secretion by autocrine and paracrine mechanisms. In the female, gonadotropin secretion varies according to the estrus or menstrual cycle stage and involves complex modes of regulation by numerous factors including the nutritional and metabolic status, age of the species and other pathological conditions. During ovarian senescence, when the ovarian feedback regulation no longer exists, FSH synthesis in the pituitary and the circulating FSH levels steadily increase. Gonadotropin biosynthesis and secretion are mostly aberrant in pituitary tumors of gonadotrope origin, often termed as non-functional or null cell adenomas. Rarely, these tumors produce high levels of functional gonadotropins. Circulating gonadotropins in blood and tissues were originally measured by radioimmunoassay (RIA) methods using

^{125}I -radioisotopes. During recent years, several non-radioactive automated methods namely ELISA and chemiluminiscence are routinely used in many basic research and clinical laboratories.

The availability of ^{125}I -labeled hormones provided a means to identify specific binding sites of gonadotropins in gonads of various species. These membrane-bound receptors were identified in low abundance on granulosa (LH and FSH receptors) and theca cells (LH receptors) within ovarian follicles. In the male, FSH receptors were localized to Sertoli cells and LH receptors to Leydig cells. Biochemical methods were used to purify these extremely labile receptors from target tissue membranes, although crude membrane receptor preparations were earlier used in radioreceptor binding assays.

LH and FSH act in a coordinated fashion in normal physiology. In the female, LH acts on ovarian theca cells resulting in production of testosterone which is then converted to estrogen by aromatase, an enzyme expressed in granulosa cells and regulated by FSH. LH also acts on granulosa cells and controls critical events leading to ovulation. After ovulation, LH acts on the corpus luteum, a structure derived from granulosa cells, theca, and endothelial cells to regulate progesterone production in many species. FSH regulates pre-antral follicle growth and granulosa cell proliferation. In the male, FSH acts during pre-pubertal period in a narrow window of time and regulates Sertoli cell proliferation and differentiation. LH binds to Leydig cells in the interstitium and regulates testosterone production, which in turn acts on Leydig cells, Sertoli cells and peritubular myoid cells to maintain spermatogenesis. A summary of gonadotropin actions is listed in **Table 2**. Despite several unique species-specific characteristics, in the majority of instances, gonadotropin signaling is mediated by the protein kinase-A and cAMP pathway. Several in vitro studies indicate that other pathways involving MAP kinase and AKT pathways are also regulated by FSH. Because, gonadotropins regulate several events leading to optimal gametogenesis and steroidogenesis in both males and females, immunoneutralization approaches using specific antibodies against full-length or small peptide regions of LH or FSH hormones or their corresponding receptors were used as potential contraceptive reagents in several species.

Gonadotropin Subunit-Encoding Genes and Their Regulation

With the emergence of gene cloning and advanced molecular biology techniques, research on gonadotropins, like many other areas of reproductive physiology, also witnessed major advances. Gonadotropin subunit-encoding genes are distinct and their corresponding cDNAs were cloned, their chromosomal positions mapped and their regulation studied in vitro in immortalized gonadotrope cell lines as well as in pituitaries of different species. Similarly, the gene/cDNA sequences for LH and FSH receptors were cloned from gonads from multiple species, their chromosome positions mapped and regulation of their gene expression studied.

Both the β -subunit encoding genes typically contain three exons and two introns. Human *FSHB* gene consists of a characteristic long 3'-untranslated region. The gonadotropin subunit gene regulation is well coordinated in response to GnRH, activins and inhibins and gonadal steroids. Transcriptional regulation of each of the subunits is studied using gonadotrope cell lines encased in a dynamic perfusion cell culture system. A combinatorial cascade of several transcriptional repressors and activators regulated by various physiological factors was identified. Their specific binding sites on gonadotropin subunit gene regulatory regions were further mapped in mutagenesis experiments where the putative regions or single nucleotide base pairs were modified. Moreover, gonadotropin subunit gene expression analyses across estrus cycles were also performed in pituitaries of various species under normal physiological conditions or under conditions where steroid negative hormone feedback is removed by gonadectomy (removal of gonads, testes or ovaries) or GnRH pulses were administered or suppressed with changing characteristics such as pulse frequency, and magnitude. The common α -subunit mRNA/protein is always present in excess whereas the β -subunits are rate-limiting. High frequency pulses of GnRH favor *Lhb* and low frequency pulses favor *Fshb* gene transcription. Recent studies identified microRNAs (miRNAs), small RNAs, 21–24 nucleotides in length, bind to 3' regions of LH β and FSH β encoding mRNAs and post-transcriptionally regulate their expression.

Table 2 A summary of important biological actions of gonadotropins

Hormone	Major sites of action	Physiological role
LH	Male: Leydig cells in testis	Testosterone production
	Female: Theca cells in ovary	Androgen production
	Granulosa cells in ovary	Ovulation
	Luteal cells in ovary	Progesterone production
FSH	Male: Sertoli cells in testis	Sertoli cell proliferation
		Germ cell maintenance
	Female: Granulosa cells in ovary	Estrogen production
CG ^a	Male: Leydig cells in testis	Testosterone production
	Female: Theca cells in ovary	Androgen production
	Granulosa cells in ovary	Ovulation
	Luteal cells in ovary	Progesterone production
		Maintenance of pregnancy

^aBinds to LH receptors and acts like LH; PMSG/eCG acts like both LH and FSH.

Gene manipulation techniques have permitted cloning of the human gonadotropin subunit genes into expression vectors and subsequent expression in Chinese hamster ovary (CHO) cell lines. The secreted recombinant gonadotropins designated rec-hLH and rec-hFSH have been highly purified and are currently used for all physiological studies. Other expression systems such as insect cell (using baculovirus vectors) and yeast were also used to produce recombinant gonadotropins for structure-function studies. Cleverly designed single chain gonadotropin analogs were expressed in CHO expression systems. This strategy bypassed the need for subunit assembly step, thereby allowing design of desired mutations on these gonadotropin single chain templates. Furthermore, novel double domain (LH and FSH) and triple domain (LH, FSH and TSH) analogs were produced that contain sub-populations of dually active gonadotropin molecules. The single, dually active and triple domain analogs were efficiently secreted into the medium, bound to receptors in vitro and exhibited biological activities when injected into animal models.

The unique O-glycosylated carboxy terminal peptide (CTP) of hCG β subunit-encoding gene sequences were genetically fused to that in the LH β subunit, expressed along with the α -subunit in polarized MDCK (Madin-Darby canine kidney) epithelial cells and the secretion behavior of LH containing this chimeric LH β -CG β CTP subunit was studied. In these MDCK cells, LH normally exited from the basolateral compartment and hCG from the apical compartment. Mutant LH containing the LH β -CG β CTP subunit exited from the apical compartment similar to hCG. Similarly, hCG containing a mutant CG β subunit lacking the CTP sequence exited from the basolateral compartment like LH. These studies implicate that while hCG and LH are highly similar in structure and function, they have different secretion patterns encoded by the presence or absence, respectively, of the CTP sequence in their β -subunits.

Mutations in Human Gonadotropins

Because gonadotropins are essential for reproduction, inactivating mutations in genes encoding the hormone-specific β -subunits are rare. But, when they do occur, they result in various gonadal defects and infertility. Two types of classical inactivating mutations in *LHB* gene were identified in men. In one type, the α /LH β dimer assembly was impaired and as a result no bioactive LH was produced in the patient. In the second type, the mutant LH β -containing LH dimer did assemble and was secreted, but did not recognize the gonadal receptors. In both cases, early testis development was not impaired, the patients exhibited normal testicular descent, however, delayed puberty, reduced spermatogenesis, Leydig cell hypoplasia and suppressed testosterone were noted. Therapy with hCG alleviated the gonadal and fertility problems in these patients. A third type affected the splicing event and resulted in an abnormal inclusion of second intronic sequences in *LHB* mRNA. Chronic testosterone treatment in conjunction with high endogenous FSH levels perhaps restored the normal testicular volume in these men. Their sister harboring the same inactivating mutation in the *LHB* gene had normal female reproductive tract growth. She displayed cystic ovaries and oligomenorrhea (infrequent menstrual cycles) with low levels of circulating estrogen. Estrogen did stimulate her ovarian follicle growth but hCG supplementation was absolutely required for ovulation induction.

Inactivating mutations in the human *FSHB* gene were also reported. Most of these are located in exon 3 and result in production of a truncated FSH β protein that fails to assemble with the α -subunit and hence FSH dimer is absent in these patients. In some patients, FSH heterodimer is formed but cannot bind to the receptor and transduce the signals in gonads. Men with mutations in *FSHB* gene present variable testis volume but are azoospermic and infertile. Bio and immunoactive FSH levels are undetectable and LH and testosterone values vary in these patients and some exhibit Leydig cell hyperplasia. Women with mutations in *FSHB* gene present common phenotypic features such as primary amenorrhea, low levels of serum FSH and estradiol and elevated LH. These women fail to respond to GnRH stimulation because bioactive and immunoactive FSH is unmeasurable indicating defective FSH dimer assembly as a result of formation of a mutant FSH β subunit. Exogenous FSH treatment rescues the ovarian folliculogenesis defects by promoting antral follicle formation. In addition to inactivating mutations in gonadotropin β -subunit encoding genes, activating and inactivating mutations in their cognate gonadotropin receptors (*LHR* and *FSHR*) were also reported. These mutations manifest in defects in reproductive function as a result of failure of normal gonad development.

Genetically Modified Mouse Models for Gonadotropins

The gonadotropin gene and protein sequences are relatively highly conserved between mice and humans. Hence, mouse genome manipulation techniques provide a convenient in vivo model system to study gonadotropin synthesis, secretion and action in a whole animal context. In one approach, gain-of-function effects of gonadotropins were tested by overexpressing individual gonadotropin subunits or both subunits separately but simultaneously in the same transgenic mouse and the consequences studied. Either a homologous or a heterologous tissue/cell specific promoter was used for directing the transgene (cDNA or gene) expression directly into gonadotropes or ectopically in tissues other than pituitary. In a second approach, loss-of-function mutations, were first created in mouse embryonic stem cells in a heterozygous state and the mutations propagated via germline transmission. Subsequently, homozygous mutant (knockout or null) were obtained by crossbreeding. A functional rescue was feasible by introducing the gain of function transgene onto the null genetic background.

During mouse pituitary development, the common α -subunit encoding gene (*Cga*) is activated first followed by LH β and finally FSH β in gonadotropes. Later, it is also activated in thyrotropes within the pituitary where it heterodimerizes with the TSH β subunit to produce TSH. Targeted overexpression of a human *CGA* transgene in pituitaries or ectopically in multiple tissues of transgenic mice did not result in any overt phenotypes and the mice were normal without any reproductive deficits. The in vivo physiological

role of the α -subunit was demonstrated by a loss of function mutation by which the α -subunit encoding gene was deleted and the α -subunit was absent from birth in these null mice. *Cga* null mice lacked both gonadotropins (LH, FSH) and thyrotropin because α -subunit is required for production of all three heterodimeric hormones. These mice exhibit profound hypothyroidism and develop thyrotrope tumors at old age. Both ovaries and testes were formed normally in these infertile mutant mice indicating early gonad formation is not dependent on circulating gonadotropins.

Gain-of-function effects of LH were studied by pituitary targeted expression of an LH analog, called LH β -CTP using a transgene encoding the carboxy terminal sequence from hCG β fused in frame with the LH β -sequence. In this way, LH remained for longer periods of time in serum of these transgenic mice. These mice initially developed hemorrhagic ovarian cysts and depending on the genetic background, also eventually developed ovarian granulosa cell tumors. Two other LH gain of function transgenic mouse models were also developed. In these models, hCG α and β subunit encoding transgenes were ubiquitously expressed in multiple tissues either by a ubiquitin C or a mouse metallothionein-I promoter. This ectopic expression of hCG in multiple tissues caused various phenotypes in both the sexes including hyperandrogenemia, Leydig cell hyperplasia and Leydig cell tumors, impaired spermatogenesis in transgenic males and ovarian cysts, thecal cell expansion and development of mammary tumors and estrogen-dependent lactotrope hyperplasia/tumors in female mice.

Because both LH and FSH are absent in *Cga* null mice, to independently study the loss of function effects of LH, *Lhb* null mice were developed. In the absence of LH β subunit and hence LH heterodimer from birth, male mice were infertile, exhibited hypogonadism and demonstrated severely suppressed intra testicular and circulating testosterone. Leydig cells were developmentally arrested and no mature adult type Leydig cells that normally produce testosterone were present in the testes. Spermatogenesis was arrested at the round spermatid stage and no elongated spermatids and mature sperm were present in the mutant testes. *Lhb* null female mice were also infertile and demonstrated suppressed levels of serum estrogen and progesterone. Ovarian histology showed most of the follicles developed up to the antral stage but pre-ovulatory follicles were absent. A prominent thecal layer was evident but all the LH-regulated genes in thecal cells were suppressed in ovaries of mutant mice. Administration of exogenous hCG to immature males and superovulation of immature females (by a combination of equine CG and hCG) resulted in rescue of *Lhb* mutants.

Targeted overexpression of a human *FSHB* transgene in gonadotropes of transgenic mice was also achieved. The human *FSHB* transgene was expressed two- to threefold higher than the endogenous mouse *Fshb* gene and was regulated similarly in mouse pituitaries. An interspecies hybrid FSH dimer, consisting of mouse α - and human FSH β , was assembled and efficiently secreted because the serum FSH levels were elevated in these mice. Male transgenic mice showed a marginal increase in testis size and normal testosterone levels. Both male and female transgenic mice were normal and did not exhibit any reproductive deficits. Human FSH was also ectopically expressed from multiple tissues in another transgenic line by using a ubiquitously active mouse metallothionein-1 promoter. This ectopic expression resulted in production of very high levels of serum FSH in these transgenic mice. Male transgenic mice exhibited enlarged seminal vesicles, elevated testosterone levels in serum and reduced testis size with apparently normal spermatogenesis but these males were infertile. Female transgenic mice were infertile and exhibited massively hemorrhagic ovarian cysts with totally disrupted folliculogenesis. These mice exhibited elevated serum testosterone and estrogen and died early around 12–14 weeks due to kidney defects.

Ectopic expression of hFSH was achieved by targeting human *CGA* and *FSHB* cDNA transgenes using a rat insulin II promoter and introducing them onto hypogonadal (*hpg*) null genetic background by crossbreeding. The *hpg* mice harbor a mutation in the GnRH-encoding gene resulting in loss of functional GnRH and hence both LH and FSH were severely suppressed in these mutant mice. This genetic strategy permitted direct assessment of physiological effects of only ectopically expressed FSH in the absence of endogenous LH. Biologically active human FSH partially rescued phenotypes in *hpg* male mice, but testosterone supplementation fully rescued them. Female transgenic mice expressing human FSH on a *hpg* genetic background demonstrated increased ovarian follicle reserve and increased antral follicle development. Those transgenic mice not on the *hpg* background also demonstrated premature ovarian failure as a result of accelerated ovarian aging.

FSH loss of function condition was created by selectively deleting the FSH β subunit-encoding gene in mice. The resultant *Fshb* null male mice showed reduced testis size, Sertoli cell number and a correspondingly reduced number of sperm as well as reduced sperm motility. Qualitatively, spermatogenesis was normal with all stages apparent in the mutant testes. Leydig cell number per testis remained the same and these mice demonstrated normal circulating testosterone levels. Interestingly, loss of FSH in mice did not affect male fertility unlike in men with inactivating mutations in the human *FSHB* gene. Unlike males, female *Fshb* null mice were infertile. They were anovulatory and demonstrated hypoplastic ovaries with a block in ovarian folliculogenesis at the pre-antral stage. There were no corpora lutea present in the mutant ovaries. In a pharmacological rescue approach, superovulation rescued *Fshb* female null mice and resulted in normal one-cell number of embryos confirming that FSH responsiveness was not lost in *Fshb* null mutant female mice.

Fshb null mice were also genetically rescued. This was achieved in two independent ways. In one approach, the 10 kb human *FSHB* transgene was introduced onto *Fshb* null genetic background. This gonadotrope-targeted human *FSHB* transgene fully rescued *Fshb* null mice. Testis size was restored, sperm number and motility reverted back to normal levels. Female mice showed normal ovarian folliculogenesis, ovulated normally and became fertile. In a second approach, low levels of human FSH were ectopically expressed and this resulted in full rescue of male mice but the rescue was somewhat incomplete in female mice. This suggested pituitary-derived but not ectopically expressed FSH was more efficient for a full functional rescue of *Fshb* null mice. *Fshb* null mice proved very useful in a number of other physiological and genetic studies in male and female reproductive physiology.

More recently, genetic rescue of *Fshb* null mice was achieved using constitutively secreted and re-routed FSH released via the LH secretory pathway. In these studies, a human LH β carboxy terminal heptapeptide encoding DNA sequence was genetically fused to that of human FSH β encoding gene sequence and the resultant *FSHB* transgene was introduced onto *Fshb* null genetic background. For comparison, the conventional wild-type human *FSHB* transgene was similarly introduced onto the *Fshb* null background. The mutant FSH β containing FSH dimer entered the LH secretory pathway and was released in response to acute GnRH treatment, similar to endogenous LH and unlike that of constitutively released FSH dimer (containing the FSH β subunit encoded by the wild-type human *FSHB* transgene). The mutant FSH expressing female mice demonstrated vastly improved and prolonged reproductive performance, producing large number of ovulations as a result of suppressed ovarian follicular atresia. Thus, the target cells (ovarian granulosa cells) can effectively decode the pattern of FSH signal inputs and respond distinctly.

Extra-Gonadal Actions of Gonadotropins

The central dogma that gonadotropins regulate gonadal function by binding to gonadal cell receptors has been challenged. In a series of in vitro studies, extra-gonadal actions of hCG were uncovered in many different tissues that express LH/CG receptors. Recently, extra-gonadal expression of FSHRs and FSH actions via these receptors were also identified. Significant effects of FSH signaling in bone osteoclasts, and white and brown adipocytes were noted particularly with implications to age-related bone loss and visceral adiposity in post-menopausal women. In ovariectomized animal models, a blocking polyclonal antibody against FSH reduced both bone loss and enhanced conversion of white to brown adipose tissue.

Clinical Applications of Gonadotropins

Human gonadotropin preparations purified from pituitary and urine sources were used for clinical research in the past. However, recombinant gonadotropins expressed in mammalian cell expression systems replaced the earlier preparations and have now been in use for various human in vitro fertilization protocols at the clinic. These recombinant gonadotropins are routinely used for ovarian follicle induction in vivo and follicle maturation in vitro. These preparations are pathogen-free and thus safe for human use. Elegant molecular cloning techniques have also allowed expressing improved versions of gonadotropins such as single chain gonadotropin analogs in which the two gonadotropins subunits are genetically fused in tandem. A long-acting FSH analog with enhanced serum half-life of FSH was also generated by genetically fusing the DNA sequence encoding the carboxy terminus of hCG β to 3'-end of DNA sequence encoding the human FSH β subunit. This FSH analog is currently approved for use in human IVF protocols in some countries. Although the primary goal of recombinant human gonadotropins is to benefit human reproductive healthcare, recombinant homologous hormones are equally efficacious in many veterinary/agricultural livestock species.

Acknowledgments

Work done in the Author's laboratory is supported in part by National Institutes of Health Grants AG029531, CA166557, HD081162, AG056046, and The Makowski Foundation. The author expresses his sincere thanks to Dr. George Bousfield for critically reading and his comments on the manuscript. This chapter is dedicated to the memory of Dr. P. Michael Conn who deceased in November 2016.

Gonadotropin Receptors

Kirsten S Eckstrum and Lori T Raetzman, University of Illinois at Urbana-Champaign, Urbana, IL, United States

Introduction

The gonadotropin receptors (luteinizing hormone receptor (LHR) and follicle stimulating hormone receptor (FSHR)) play critical roles in male and female reproduction. LHR and FSHR belong to the G protein coupled receptor (GPCR) family and have a large extracellular domain, a transmembrane segment consisting of seven membrane spanning α helices, and a short intracellular domain. These receptors, found in male testes and female ovaries, bind to the gonadotropins, luteinizing hormone (LH) and follicle stimulating hormone (FSH), secreted from the gonadotroph cells of the anterior pituitary. Activation of these receptors leads to development of the gonads and production of sex steroids. In both males and females the production of hormones through the gonadotropin receptors is important for proper development and functioning of the hypothalamic-pituitary-gonadal (HPG) axis. The LHR is also called LH/hCG receptor due to its ability to bind human chorionic gonadotropin, a hormone produced by the placenta during pregnancy. Here we will focus on the structure and function of the gonadotropin receptors in the female ovaries. The ovary has two fundamental functions: one is to develop oocytes and the second is to produce steroid hormones. The gonadotropin receptors have roles in each of these processes.

Gene to Protein

Both the gonadotropin receptor genes (*LHR* and *FSHR*) in humans are located on chromosome 2 and are separated by about 200 kb. In the mouse, they are located on chromosome 17, and in the rat on chromosome 6. Interestingly, for both *Lhr* and *Fshr*, the extracellular domain is encoded by the first 10 and 9 exons respectively, while the transmembrane domain and the C-terminal intracellular domain are encoded by the last exon. Between these receptors, the N-terminal domain is highly conserved, whereas the C-terminal is variable. Thus, the intracellular C-terminal domain is important in specific functions of each of the receptors. *LHR* and *FSHR* transcript size varies from species to species and with different splice variants. In general, the transcript size for *Lhr* in rats ranges from 6.7 to 1.8 kb and for *Fshr* there are two predominant transcripts of 7.0 and 2.5 kb (reviewed in Menon and Menon, 2012). Once the mRNA is transcribed, it is translated into protein. LHR consists of 699 amino acids and the mature protein has a molecular mass of 75 kDa. FSHR has 678 amino acids and a molecular weight of 76.5 kDa. Precursor forms of LHR and FSHR are also detectable as well. The precursors tend to accumulate in the endoplasmic reticulum and do not bind the hormone with high affinity. The LHR precursor is a mannose-rich 68 kDa protein and the FSHR precursor is an 81 kDa mannose-rich protein. LHR and FSHR are folded in the endoplasmic reticulum by a number of chaperone proteins including calnexin and calreticulin.

Once LHR and FSHR are translated into protein, they go through protein modifications. The rat LHR has been shown to contain six N-glycans on the predicted glycosylation sites. However, if protein glycosylation is inhibited, binding of hormone is unaffected. On the other hand, FSHR was shown to be glycosylated on two of three possible sites. Interestingly, glycosylation of FSHR is necessary for proper functioning of the receptor, as deglycosylated FSHR does not bind FSH. This is because FSHR does not fold into the right conformation and move to the cell surface unless at least one of the two sites is properly glycosylated (Davis et al., 1995). The fully glycosylated form of LHR is 85 kDa and the fully glycosylated form of FSHR is 87 kDa. Soluble forms of LHR, formed from alternative splicing, also occur in the ovary. Soluble forms of LHR contain either the extracellular domain only or the extracellular and intracellular domain but no transmembrane domain. The soluble form has a similar affinity for LH as the membrane bound receptor. Therefore, the precursor, soluble, and full LHR can bind LH but only the full FSHR can bind FSH.

Interestingly, when gel electrophoresis was first done to determine the size of LHR and FSHR, only two bands were visualized for these receptors, the immature and the mature forms. However, more recently, molecular weight bands have been discovered consistent with dimeric or oligomeric forms of the gonadotropin receptors. The dimerization/oligomerization of the gonadotropin receptors is a process where the receptor self-associates in the endoplasmic reticulum and is eventually put in the plasma membrane in its self-associated form. This association of the receptors is not altered by the activation state of the receptor, meaning activation of one receptor does not cause the receptors to dimerize or cause them to break apart, however, data suggest that the transmembrane and extracellular domains of the receptors can mediate the homodimerization of the receptors (reviewed in Segaloff, 2012). Therefore, many mechanism and associations take place to get a fully functional LHR and FSHR in the cell membrane and ready to be activated.

Receptor Structure and Activation

The gonadotropin receptors are both transmembrane G-protein coupled receptors containing a large N-terminal extracellular domain. LHR and FSHR need to have such large extracellular domains because their ligands, the glycoproteins LH and FSH, are dimeric proteins consisting of an α and a β subunit, making these rather large proteins. Like other G-protein coupled receptors, LHR and FSHR have seven transmembrane α helices with three extracellular loops and three intracellular loops, and a short intracellular or cytoplasmic domain. Normally the receptors remain in an inactive state. Gonadotropin receptor activation occurs in two

steps. First, there is high affinity hormone binding to the extracellular domain. Second, there is hormone or extracellular domain interaction with the extracellular loops of the transmembrane domain to cause receptor activation via a conformational change, leading to activation of intracellular signaling cascades.

The ligands for the receptors share a common α subunit, but each have distinct β subunits. The extracellular domain has irregular leucine rich repeats that create successive β -strands and α -helices which makes a cusped structure with a β -sheet at the concave surface of the cusp. The hormone ligands of these receptors bind in the cusp region. The interaction with the extracellular loops of the transmembrane domain is important for receptor activation and the large extracellular domain helps to increase the binding affinity. Mutations of the third extracellular loop of LHR impairs receptor activation without altering hormone binding. In FSHR, mutations in the first extracellular loop impair hormone binding and receptor activation. Therefore, all three of the extracellular domains play a role in hormone binding and mutations in any of the three extracellular loops can affect receptor activation and/or hormone binding (reviewed in [Banerjee and Mahale, 2015](#)). The precise mechanism by which the interaction between the ligand and the receptor activates the receptor is unknown, however, there are three proposed models. First, the portion of the ligand bound to the extracellular domain interacts with the hinge region of transmembrane helices, leading to receptor activation. Second, the interaction of the ligand on the extracellular domain causes the extracellular domain to interact with the transmembrane helices to cause receptor activation. Third, the extracellular domain normally causes an inhibitory effect on the transmembrane region, keeping it in the inactivated state, and binding of the ligand relieves the inhibitory effect (reviewed in [Menon and Menon, 2012](#)). Despite the lack of understanding of precisely how the receptor is activated, it is known that the extracellular domain, extracellular loops, and the ligand are all important, and that specific binding leads to a conformational change that conducts the signal into the cell.

The transmembrane domain is the site of signal transduction. Once the hormone binds the receptor, it is phosphorylated by G-protein related kinases. The receptor is then functionally uncoupled from the G-protein (Gs), meaning the G protein dissociates to bind with other factors in the signal transduction pathway. Once Gs becomes uncoupled, it activates adenylate cyclase, resulting in increased intracellular cyclic AMP (cAMP). This then leads to activation of protein kinase A (PKA) ([Fig. 1](#)). LHR and FSHR are also able to activate signaling pathways leading to increased inositol triphosphate (IP3) production, increased calcium, and activation of mitogen-activated protein kinases (MAPK) (reviewed in [Themmen and Huhtaniemi, 2000](#)). Additionally, these receptors have been shown to activate Akt pathways. Signaling is terminated in part by either desensitization or down regulation of LHR and FSHR expression, mechanisms to prevent excessive stimulation. Desensitization involves receptor phosphorylation and uncoupling to signaling pathways. For down regulation, the receptor brings in beta arrestins, which assist in internalization of hormone-receptor complex. The three intracellular loops play roles in either the internalization or phosphorylation process (reviewed in [Banerjee and Mahale, 2015](#)). In addition to receptor internalization, receptor mRNA levels are also reduced upon prolonged stimulation, which will further lead to receptor downregulation. Overall, once the gonadotropin receptors are activated, there are series of signaling cascades initiated that lead to many effects within the cells, including additional signaling through protein modification by phosphorylation and activation of gene transcription. Importantly, changes in the cell will be important in folliculogenesis and steroid hormone production.

Fig. 1 Schematic of gonadotropin receptor signaling. When the gonadotropin (LH or FSH, purple) binds to its receptor (blue structure) in the cell membrane, a signaling pathway is activated through adenylate cyclase (AC) leading to protein kinase A (PKA) activation.

Gonadotropin Receptors in Follicular Development

The oocytes develop inside a follicle that consists of granulosa and theca cells. The gonadotropins, LH and FSH, are important in folliculogenesis or development of the follicle, induction of ovulation, and overall reproductive capability of the female. Primordial follicles remain quiescent until selected to become a primary follicle. Once primordial follicles are recruited, they progress to primary follicles containing a single layer of cuboidal granulosa cells and a basement membrane. The primary follicle is considered the first stage of the growing pool of follicles. Next, the follicle progresses to a secondary follicle containing several layers of granulosa cells surrounding the oocyte and a layer of theca cells. Eventually the granulosa cells secrete fluid to the center of the follicle, which collects to create a fluid filled spaces. This marks the tertiary follicle or early antral follicle. Tertiary follicles also have multiple layers of granulosa and theca cells. With increasing secretions from the granulosa cells, the fluid filled spaces fuse into what is termed the antrum. The antrum eventually becomes large enough so that it nearly encompasses the oocyte. At this point the follicle is called the preovulatory or Graafian follicle. It is from this follicle that the fertilized oocyte will be released from (reviewed in [Boron and Boulpaep, 2009](#); [Sánchez and Smitz, 2012](#)). This process of follicular growth, once initiated, continues until the oocytes is ovulated or degraded. At any given point in the reproductive cycle, an ovary will possess follicles of all the different stages.

To understand how the gonadotropin receptors function in follicular development and hormone production, it is important to know when and where they are expressed during the cycle described above. In humans and rodents, LHR protein and mRNA expression are not detected in primordial or primary follicles. LHR begins to be detected in theca cells of small antral follicles and is present in granulosa cells of the late antral follicles. The LH surge results in downregulation of LHR mRNA in rodents, but then expression reappears in the corpus luteum. On the other hand, primordial follicles do not express full length *FSHR* mRNA. In humans, *FSHR* protein is detectible in follicles beginning in the secondary stage and FSH binding is detectible in pre-granulosa cells that have matured to cuboidal forms. Although granulosa cells express *FSHR* and can respond to exogenous gonadotropins before the antral phase, follicular growth prior to the antral phase is not dependent on gonadotropins (reviewed in [Misrahi et al., 1998](#); [Yamamoto et al., 1992](#)). *FSHR* mRNA is present in the antral through pre-ovulatory follicle, but levels decrease in the corpus luteum.

There are three key phases of the gonadotropin receptor activity in follicular development: initial follicle development, FSH-dependent progression, and LH-responsive maturation. Initial follicle development from primordial to secondary follicle is believed to be *independent* of gonadotropin involvement. This has been determined based on evidence that mice that lack gonadotropin releasing hormone (GnRH), and thus have low FSH and LH levels, still show follicular growth up to the pre-antral stage. Similarly, women with hypogonadotropic hypogonadism, who have low levels of gonadotropins, have follicular development up to the primordial follicle. If exogenous gonadotropins are given to patients with this condition, ovulation and pregnancy can be obtained ([Sungurtekin et al., 1995](#)). This suggests that the ovaries already had a population of follicles that achieve their basal growth independent of the actions of gonadotropin receptors and administration of gonadotropins allowed them to progress to antral follicles.

It is clear that FSH is required for development of large antral follicles, bringing us to the FSH-dependent progression phase. With rising levels of FSH secreted from the anterior pituitary gland, a cohort of follicles will progress to further stages of development during the follicular phase of the ovarian cycle. Gonadotropins, in particular FSH, are important for sustained growth. FSH acts through its receptor on the granulosa cell to stimulate proliferation of granulosa cells leading to increased layers of granulosa cells. It also causes locally produced growth factors and formation of glycosaminoglycans that are then secreted to create the antral fluid (reviewed in [Hillier, 1994](#)). Dependence on FSH during folliculogenesis is low during basal growth and becomes more and more dependent as the follicle progresses. Granulosa cell growth is impaired when gonadotropins are low or absent, so there are less follicles in the growing phase without gonadotropins. Additionally, giving more gonadotropins accelerates follicular growth in experimental systems. However, gonadotropin receptor signaling is not the only determinant of follicular growth as many factors have also been shown to be important, including estradiol, insulin-like growth factor (IGF) and IL-6 (reviewed in [Matsuda et al., 2012](#)). If any of these factors are depleted or absent, the follicle will undergo atresia. The granulosa cells are programmed to be the first to undergo a form of cell death known as apoptosis if any of these pro-growth factors, including FSH, are missing.

As the follicles continue to grow, they become selectable, meaning they can be chosen to ovulate. During the early follicular phase, one follicle is selected to ovulate in humans, the most developed and healthy of all the follicles. The dominant follicle has been hypothesized to release follicular regulatory proteins to prevent the development of less developed follicles. In terms of hormonal regulation, the selected dominant follicle begins expressing FSH-induced aromatase activity, induces expression of LHR, and starts producing estrogens instead of androgen. It is also the one with the lowest FSH threshold. As the follicle develops, it becomes more and more sensitive to FSH. In the latter half of the ovarian cycle, FSH levels decrease due to increased estradiol and inhibin. Despite the decrease in FSH, the preovulatory follicle remains responsive to circulating FSH. The reason for increased responsiveness of pre-ovulatory follicles compared to small antral follicles is not entirely understood as smaller antral follicles and pre-ovulatory follicles express a similar number of FSH binding sites (reviewed in [Misrahi et al., 1998](#)). However, it may be because the dominant follicle is more vascularized compared to the less developed follicles thus increasing the amount of FSH the dominant follicle receives.

Follicular development is not only sensitive to FSH, but it is also sensitive to LH during the third stage, LH-responsive maturation. By the mid-follicular phase LH receptors are present on the theca cells and on granulosa cells, whose expression was stimulated by FSH signaling through *FSHR* (reviewed in [Richards et al., 1987](#)). The increased presence of LHR in the dominant follicle protects the follicle from the fall in plasma FSH concentrations and the follicle becomes more dependent and responsive to LH. There is a threshold level of LH that is required for follicular development and maturation during this stage. Too little LH and there is no androgen or estrogen synthesis, too much LH and granulosa cell proliferation is inhibited and follicles become atretic or go

through premature luteinization. As the pre-ovulatory follicle continues to grow there are increasing amounts of estrogen being made by this follicle. This estrogen then causes a positive feedback event leading to a LH surge mid-cycle. This surge causes the egg to finish meiotic maturation, it inhibits granulosa cell division and begins luteinization of the follicle. LH is primarily responsible for the shift in steroid production after the LH surge from estrogen to progesterone. Furthermore, in the corpus luteum the breakdown of the basal lamina allows cholesterol to get to the granulosa cells for progesterone production (reviewed in [Amsterdam et al., 1992](#)). Thus, both FSHR and LHR are of critical importance in the ovarian cycle. FSHR is more critical in the follicular phase while LHR is more important in the luteal phase. However, both receptors are necessary at the same time for estrogen production in the two-cell two-gonadotropin model.

Steroid Biosynthesis: The Two-Cell, Two-Gonadotropin Hypothesis

LHR and FSHR play important roles in steroid biosynthesis of estrogens via a two-cell concerted system. The two cells are theca and granulosa cells and the two gonadotropins are LH and FSH. Theca cells are the more superficial cells of the follicle making them close to blood vessels so they can easily pick up cholesterol. Cholesterol is the first essential component in steroid biosynthesis. Theca cells express LHR only, not FSHR. When LH binds its receptor, it increases the synthesis of steroidogenic acute regulatory protein (STAR), leading to an increase of cholesterol in the mitochondria. LHR signaling also increases the expression of enzymes necessary to produce androstenedione and testosterone in the theca cell including p450 side-chain cleavage (CYP11A1), 17 α -hydroxylase (CYP17A), and 3 β -hydroxysteroid dehydrogenase (HSD3B). Here, steroid biosynthesis in the theca cell ends.

The next step is the androstenedione created in the theca cell freely diffuses through the lamina basalis, or basement membrane, into the granulosa cells. FSH binding to FSHR initiates a signal cascade in the granulosa cell to stimulate expression of the enzyme aromatase, allowing the granulosa cell to convert the testosterone from the theca cell into estradiol, one of the main estrogens. Estradiol is then released into the blood stream. Interestingly, granulosa cells also express LHR however, they only create their own testosterone during the luteal phase of the menstrual cycle. This is because granulosa cells are located more centrally in the follicle where there are not many blood vessels to provide cholesterol to the cells. However, in the luteal phase, the theca and granulosa cells transform into the theca-lutein and granulosa-lutein cells respectively, which make up the corpus luteum. The corpus luteum is more highly vascularized allowing for granulosa-lutein cells to pick up cholesterol from the blood stream. However, another problem exists for the granulosa cells in making testosterone in that they lack the necessary enzyme, 17 α -hydroxylase, which converts progesterone into 17 α -hydroxyprogesterone. Therefore, progesterone from the granulosa cell must diffuse to the theca cell to be converted to androstenedione (reviewed in [Boron and Boulpaep, 2009](#)). In sum, LHR stimulates the production of testosterone in the theca cells, which is sent to the granulosa cells that express aromatase, and whose activity is increased by FSHR, in order to make estrogen. Therefore, both LH and FSH are necessary and both theca and granulosa cells are necessary to make estradiol.

Relevant Mutations to Human Health

Genetic mutations in *LHR* or *FSHR* can impact reproductive function in the female. These mutations can either lead to inactivation or overactivation of the receptors. Inactivating *LHR* mutations have few effects on the early development of female sex characteristics. However, patients have a small uterus due to decreased estrogen, reduced bone mass, increased plasma LH concentrations, amenorrhoea, and anovulation. Loss of function mutations in *FSHR* show ovarian histology resembling that of the pre-pubertal period with mainly primordial and primary follicles ([Aittomäki et al., 1996](#)). Women with loss of function mutations in *FSHR* have an ovarian dysgenesis syndrome associated with delayed puberty, primary amenorrhea, and infertility. Most mutations in *LHR* and *FSHR* result in decreased expression of the mutant receptor due to misfolding of the receptor. Misfolded proteins are usually prevented from leaving the ER and become targeted for degradation. Interestingly, a mutation in the *LHR* that prevents interaction between Asp578 and Asn615 in the transmembrane helix 7 mimics the ligand occupied state of LHR and leads to a constitutively active form of LHR. Although this can cause precocious puberty (reviewed in [Shenker, 2002](#)), other studies have suggested that overexpression of LHR alone is insufficient to induce puberty in girls because both LHR and FSHR co-operate to allow steroid production in the ovary. Further, mutations in extracellular binding domain of *FSHR* that permit hCG to bind to the receptor have been associated with ovarian hyperstimulation syndrome, including fluid filled ovarian cysts and pregnancy complications. These examples illustrate the importance of normal gonadotropin receptor function in human health.

Conclusion

Taken together, the gonadotropin receptors are a unique class of GPCRs that play a vital role in ovarian development and function. Not only are the actions of LHR and FSHR important for the ovary and reproduction, as we have focused on here, but they are important for the proper functioning of the entire body because they are critical in the creation of estrogens and estrogens can affect many tissues including the brain, pituitary, mammary glands, bone, heart, and many more. Therefore, it is important to continue to study the components of these GPCR structure, activation, and function to fully understand the ovary, reproduction, and the overall human body.

Introduction

Steroid receptors (SRs) are a subfamily of the nuclear receptor superfamily, containing five classical members: estrogen receptors (ESRs), progesterone receptors (PGRs), androgen receptors (ARs), glucocorticoid receptors (GRs), and mineralocorticoid receptor (MR) (Williams-Ashman and Reddi, 1971; Toft and Gorski, 1966; Kuiper et al., 1996; Bruchovsky and Wilson, 1968; Munck and Brinck-Johnsen, 1968; Porter and Edelman, 1964). They are likely to stem from a common ancestor gene, and share highly conserved structures and functions (Thornton, 2001). SRs regulate a multitude of genes and proteins via both genomic and non-genomic pathways, leading to alterations in a wide range of biological processes (Levin, 2015; Beato and Klug, 2000; Levin and Hammes, 2016). The critical regulation of SRs in female reproduction has already been recognized (Geraghty and Kaufer, 2015; Findlay et al., 2010; Conneely et al., 2000; Zhou, 2010). This chapter summarizes the molecular structures and actions of SRs, and focuses on their functions in female reproduction.

Molecular Biology

Gene

In humans, SR genes are located at different chromosomes. ESR has two major isoforms ESR1 and 2, also called NR3A1 and 2 which is encoded by two different genes located on chromosome 6q and chromosome 14q, respectively (Gosden et al., 1986; Enmark et al., 1997). PGR, also called NR3C3, is encoded by one gene that is located at Chromosome 11q which transcribes two major isoforms PGR-A and -B (Law et al., 1987; Kastner et al., 1990). AR, also called NR3C4, is encoded by one gene on chromosome X q11-q12 (Lubahn et al., 1988). GR is encoded by gene NR3C1, located on chromosome 5q31-32 with two major isoforms GR α and GR β (Theriault et al., 1989; Hollenberg et al., 1985). MR is encoded by gene NR3C2 located on Chromosome 4 q31.1 (Morrison et al., 1990).

Protein

As shown in Fig. 1, all SRs display a modular structure comprised of six regions (A-F) (Misrahi et al., 1993): a hypervariable amino-terminal domain region A/B, a highly conserved DNA-binding domain (DBD) region C, a linker region D, a less conserved ligand binding domain (LBD) region E, and a hypervariable carboxyl-terminal domain region F (Beato and Klug, 2000). There are two transcription activation domains in SRs, one is ligand independent and located at the A/B region referred to as activation function (AF)-1, the other is ligand dependent and resides at the E region, called AF-2 (Wammark et al., 2003). Cofactors and basal transcription machinery factors can interact with AF-1 and -2 (Kumar and Thompson, 2005). Little is known about F region, but it may play a role in ESR1 transcription (Pawlak et al., 2012).

Isoforms

Protein isoforms are generated from the same gene but with distinct amino acid sequences and biological roles (Gunning, 2006). Alternative promoter, splicing and translation initiation sites are common mechanisms of producing protein isoforms (Chen and Manley, 2009; Pal et al., 2011; Kochetov, 2008), and are identified in SRs.

Multiple promoters reside at SR genes. At a minimum, the number of promoters is eleven for ESR1 (Kos et al., 2001; Zou et al., 2009; Okuda et al., 2003), four for ESR2 (Hirata et al., 2001; Shoda et al., 2002; Smith et al., 2010; Lee et al., 2013), five for PGR (Yamanaka et al., 2002; Hirata et al., 2000, 2002; Saner et al., 2003; Kastner et al., 1990), nine for GR (Palma-Gudiel et al., 2015; Breslin et al., 2001; Turner and Muller, 2005; Presul et al., 2007) and two for MR (Zennaro et al., 1995), but only one identified for AR so far (Ahrens-Fath et al., 2005; Dehm et al., 2008; Tilley et al., 1990).

Coupling with the multiple promoters, alternative splicing produces dozens of transcription isoforms by intron/exon skipping, inserting, or replicating. Many SR transcription isoforms have been demonstrated with physiological and/or pathological functions, such as ER β cx (Herynk and Fuqua, 2004), PGR-C, -M, -S (Wei et al., 1990; Cork et al., 2008), AR-V7, -V9 (Lu et al., 2015; Dehm and Tindall, 2011), GR γ , GR-A and GR-P (Moalli et al., 1993; Ray et al., 1996), and MR248, MR260, MR+4 (Bloem et al., 1995; Zennaro et al., 2001) etc.

Fig. 1 Schematic diagram of the protein structure of steroid receptors (SRs). SRs display a modular structure comprised of six regions (A–F). AF1, activation function 1 is located at A/B region; DBD, DNA binding domain is located at C region; LBD, ligand binding domain; AF2, activation function 2 are located at E region.

Alternative translation further increases the number of protein isoforms. For example, 8 alternative translation initiation sites (TIS) have been identified in GR, thus 8 translation isoforms could be generated from a single GR transcription isoform, such as GR α and β (Lu and Cidlowski, 2005). In the same paper, the authors predict more species conserved TIS at the N-terminal of ESR1, PGR, AR, and MR (Lu and Cidlowski, 2005). Several of these internal TIS have already been identified as truly functional alternative translational start sites (Pascual-Le Tallec et al., 2004; Barraille et al., 1999; Wilson and McPhaul, 1994; Chantalat et al., 2016).

Coregulators

Transcription coregulators are molecules that interact with nuclear receptors (NRs) to regulate the gene transcription (Lonard and O'Malley, 2012; Millard et al., 2013). They are recruited by the NRs in a dynamic arrangement to modify the transcription factors including NRs, chromatin, and other coregulators (Millard et al., 2013). Most coregulators can either activate or repress the transcription (Lonard and O'Malley, 2007). To date, more than 300 coregulators can interact with SRs (Obeid et al., 2016).

These coregulators not only act as a physical adaptor, but also exert some enzymatic activities, including the acetyltransferase activity associated with steroid receptor coactivator-1 (SRC-1) family and CREB binding protein (CBP)/p300 coactivator family (Dasgupta and O'Malley, 2014), the methyl transferase activity of protein arginine methyltransferase (PRMT) 1 and 5 (Wysocka et al., 2006), the ATPase dependent chromatin remodeling by the switch/sucrose non-fermentable (SWI/SNF) complex (Roberts and Orkin, 2004), ubiquitin-ligase activity of E6-associated protein (E6-AP) and receptor potentiating factor 1 (RPF1) (Ramamoorthy and Nawaz, 2008; Imhof and McDonnell, 1996).

Actions

Nuclear SRs directly regulate gene transcription through genomic pathways, while membrane or mitochondria SRs might regulate the gene or protein expression through non-genomic pathways which will not be discussed in this chapter (see Fig. 2; Losel and Wehling, 2003; Levin, 2015; Schwartz et al., 2016).

For the genomic actions, SRs bind to a specific DNA sequence in the chromatin, called hormone response element (HRE) (Klinge, 2001; Glass et al., 1988; Umesono and Evans, 1989; Klein-Hitpass et al., 1986; Aranda and Pascual, 2001). After binding to the HRE, SRs recruit multiple enzymes to modify the chromatin state in preparation of the gene transcription (Beato et al., 1995; Metivier et al., 2006). The recent development of high throughput sequencing techniques has unveiled the DNA binding patterns of SRs throughout the genome.

Genomic analysis of SR binding sites has demonstrated that only a small fraction of SR binding sites are within the proximal promoter of target genes, while the majority are at the enhancers, the distal regulatory regions (Ballare et al., 2013; Carroll et al., 2006; Wang et al., 2011; Le Billan et al., 2015; Yu et al., 2010; Hewitt et al., 2012). The distribution patterns of these binding sites are markedly changed with different species, cell lines, and experimental designs (O'Hara et al., 2014; Le Billan et al., 2015; Aranda and Pascual, 2001; Rubel et al., 2012; Handel et al., 2013).

Fig. 2 Molecular mechanism of steroid receptor (SR) actions. Non-genomic actions of SR could be mediated by membrane SR and its downstream signaling pathways. SR genomic actions could be induced by ligand in a ligand dependent pathway, or growth factors, cytokines, etc. and its downstream kinases in ligand independent pathways. In the nucleus, SR directly binds to the chromatin at HRE, or tethers or co-binds with TF to the chromatin to regulate the gene transcription. *SR*, Steroid receptor; *HRE*, Hormone response element; *TF*, Transcription factor.

In addition to the direct binding, more often, SRs bind to the chromatin via tethering, or co-binding with other transcription factors (Owen et al., 1998; Gao et al., 2001; Gizard et al., 2005; Stender et al., 2010; Kassel and Herrlich, 2007; Reddy et al., 2009). The effects of the crosstalk between SRs and other transcription factors on transcription can be either positive or negative (Ratman et al., 2013).

Based on the presence of ligand, the genomic actions of SRs could be divided into ligand dependent or independent actions.

Ligand Dependent Actions

The classical model of SR actions presumes that SRs reside in the cytoplasm in association with heat shock proteins, once activated by its ligand, SRs transiently dissociate from the complex, dimerize, translocate to the nucleus and bind to the chromatin to regulate the transcription (Beato, 1989; Jensen et al., 1968; Pratt et al., 1989). Despite of its popularity, several problems arise from the classical model. One is that unliganded SRs do not necessarily reside in the cytoplasm. It is well known that ESR, PGR, and MR are mainly in the nucleus even in the absence of ligand (Greene et al., 1984; Perrot-Applanat et al., 1985; Wikstrom et al., 1987; Lombes et al., 1990). To make it more complicated, SR isoforms, such as PGR-A, PGR B, GR α , and GR β , may reside in different cellular compartments (Nadeem et al., 2016; Leslie et al., 2005; Oakley et al., 1997; Wan et al., 2001). More importantly, ligand recruitment is not essential for SR genomic actions as will be discussed below.

Ligand Independent Actions

In the absence of cognate ligand, ESR, PGR, AR and GR can be transcriptionally activated by a large variety of signals, such as Epidermal growth factor (EGF), insulin, dopamine, cytokine, etc. (Bennesch and Picard, 2015). As ligand binding can recruit kinase to activate SRs through phosphorylation (Lannigan, 2003; Trevino and Weigel, 2013; Koryakina et al., 2014; Bagchi et al., 1992), ligand independent kinase recruitment could also activate SRs. For example, Mitogen activated protein kinase (MAPK), Protein kinase A (PKA), and Protein kinase B (AKT) are recruited to activate ESR (Maggi, 2011; Becker et al., 2011); MAPK, Cyclin dependent kinase 2 (CDK2) and casein kinase 2 (CK2) are recruited to activate PGR (Hagan et al., 2012); Protein kinase C (PKC) and Rho GTPase are recruited to activate AR (Ponguta et al., 2008; Chan and Dehm, 2014; Lyons et al., 2008); and MAPK, Tumor necrosis factor (TNF) α are recruited to activate GR (Verhoog et al., 2011; Kotitschke et al., 2009) etc.

After activation, unliganded SRs bind to the chromatin to regulate gene transcription. Chromatin immunoprecipitation-sequencing (ChIP-Seq) analysis identifies the binding sites of ESR, PGR and GR with chromatin at ligand free conditions (Ahmad and Kumar, 2011; John et al., 2011; Rubel et al., 2012; Ballare et al., 2013). And the ligand independent GR bindings at the promoter regions are found to up-regulate several gene expressions (Ritter et al., 2012; Ritter and Mueller, 2014).

Specific Topics

SRs are expressed throughout the female reproductive system and act as critical regulators. In this chapter, we will focus on their functions in hypothalamus, pituitary, ovary, uterus, mammary gland and placenta. The hypothalamus and pituitary are the central part of the reproductive system. They coordinate with the female gonad, the ovary, to establish the hypothalamus–pituitary–gonad (HPG) axis to regulate the peripheral reproductive organs including the uterus, mammary gland and the placenta.

ESR

ESRs play a crucial role in the female reproductive system (Hamilton et al., 2014).

Hypothalamus

ESR1 and ESR2 are expressed in specific nuclei in the hypothalamus (Kuiper et al., 1998). Results from genetically modified mouse models indicate that ESR1 is the predominate regulator of female reproduction at the level of the central nervous system (Couse and Korach, 1999; Herbison, 1998; Wintermantel et al., 2006; Jayes et al., 2014). However, the importance of ESR2 in the central regulation of female reproduction has also been suggested (Hu, 2009; Weiser et al., 2008; Acevedo-Rodriguez et al., 2015).

In the hypothalamus, Gonadotropin-Releasing Hormone (GnRH) neurons, the central regulator of the reproductive HPG axis, is under the control of estrogen. Although the direct estrogen actions on GnRH neurons are still elusive (Butler et al., 1999; Roy et al., 1999; Martinez-Morales et al., 2001; Hu, 2009; Ng et al., 2009), it has been well established that GnRH neurons are innervated by ESR1 expressing neurons in other regions, such as the anteroventral periventricular nucleus (AVPV), the arcuate nucleus (ARC) and preoptic and anterior hypothalamic divisions of the periventricular nucleus (PVPOA) (Smith et al., 2005; Clarkson et al., 2008). ESR1 signaling in Kisspeptin (Kiss) 1 neurons at AVPV and ARC is essential for GnRH neuron activities (Skorupskaitė et al., 2014).

In addition to regulating the HPG axis, ESR1 is also directly involved in the neural circuits of some reproductive behaviors, such as female sexual receptivity which is initiated by ESR1 in the ventromedial hypothalamus (VMH) (Musatov et al., 2006; Kudwa and Rissman, 2003; Dominguez-Ordóñez et al., 2016). Maternal behaviors are enhanced by ESR1 actions in the medial preoptic area (Pena and Champagne, 2015).

Pituitary

ESR1 is the major isoform of ESRs in the pituitary. ESR1 primes the pituitary for the GnRH-induced luteinizing hormone (LH) surge (Kim et al., 2011). Pituitary-specific ESR1 null mice show dysregulation of the HPG axis (Singh et al., 2009), which could be partially rescued by the induction of ESR2. This demonstrates both ESR1 and 2 functions in the pituitary (Sanchez-Criado et al., 2012). Furthermore, ESR1 is important for the proliferation, apoptosis, prolactin expression and secretion of lactotrope in the anterior pituitary during estrous cycle and lactation (Ben-Jonathan et al., 2008; Yin et al., 2002; Zarate and Seilicovich, 2010; Zarate et al., 2010).

Ovary

In the ovary, ESR2 is abundant in the follicular granulosa cells, while ESR1 is mainly in the thecal and interstitial cells (Heldring et al., 2007; Sar and Welsch, 1999; Drummond and Fuller, 2012). Accordingly, ESR2 is found to be essential for the development of the ovarian follicles (Drummond and Fuller, 2012). ESR2 deletion from ovarian follicles impairs follicle development and functions (Emmen et al., 2005; Couse et al., 2005; Inzunza et al., 2007) leading to subfertility of mice (Jayes et al., 2014). In contrast, ESR1 deletion has been shown to have minimal effects on follicle development (Emmen et al., 2005). However, the ovulation and folliculogenesis resulted in thecal-specific ESR1 null mice emphasizing the importance of ESR1 in the ovary (Lee et al., 2009). More interestingly, ESR1 and ESR1/2 global knockout mice have testicular structures in the ovary, which suggests the roles of ESR1 in embryonic development of the ovary (Couse et al., 1999, 2006; Dupont et al., 2000).

Uterus

Results from genetically modified mice indicate that ESR1 is the major isoform in the uterus, which is dispensable for uterine development but essential for uterine functions (Hewitt et al., 2016). In response to the cyclic levels of estrogen during reproductive cycles and pregnancy, uterine ESR1 signaling drives epithelial proliferation (Koos, 2011), increases vasculature permeability (Rockwell et al., 2002; Koos, 2011), and establishes endometrial receptivity and decidualization (Robertshaw et al., 2016). Interestingly, the action of ESR1 is not cell autonomous in the uterus. ESR1 mediates a network of paracrine signaling between uterine stroma and epithelium to regulate epithelial cell proliferation (Winuthayanon et al., 2010, 2014).

Mammary gland

Both ESR1 and ESR2 are expressed in the mammary gland (Saji et al., 2000). ESR1 is expressed at all stages of mammary gland development including embryonic, pubertal, adult virgin and pregnant stages (Mehta et al., 2014). During the embryonic stage, ESR1 is detected (Keeling et al., 2000; Lemmen et al., 1999), but not required for mammary gland development (Briskin and O'Malley, 2010). At puberty, epithelial not stromal ESR1 drives the epithelium proliferation via paracrine signaling to promote the rapid growth of mammary ducts, such as elongation and side-branching (Zeps et al., 1998; Russo et al., 1999; Clarke et al., 1997; Mueller et al., 2002; Mallepell et al., 2006). During pregnancy, ESR1 regulates ductal and alveoli development (Feng et al., 2007).

Placenta

Virtually all cellular compartments of the human term placenta express either ESR1, ESR2, or both (Bukovsky et al., 2003a, b; Kim et al., 2016). Estrogen stimulates the differentiation of trophoblast, remodeling of uterine arteries, hormone production in trophoblast cells, placenta villous angiogenesis, and proliferation of decidualized endometrial stromal cells in the metrial gland in both human and rodents (Gambino et al., 2012; Albrecht and Pepe, 2010; Furukawa et al., 2012, 2013).

PGR

Hypothalamus

In rodents, PGR is highly expressed in several hypothalamic regions, such as anteroventral periventricular nucleus (AVPV), arcuate nucleus (ARC), and ventromedial nucleus of the hypothalamus (VMH) etc. (Quadros et al., 2007; Schwarz et al., 2010; Mahfouz et al., 2016a; Sa et al., 2013), including GnRH and Kiss1 neurons located at these regions (Ng et al., 2009; Clarkson et al., 2008; Dubois et al., 2016). Estradiol induction of PGR is a critical event for GnRH surge (Brom and Schwartz, 1968; Labhsetwar, 1970; Rao and Mahesh, 1986). Especially, PGR signaling is essential for the activities of Kiss1 neuron (Gal et al., 2016; Stephens et al., 2015; Leite et al., 2016). In addition, progesterone facilitates and inhibits female sexual behavior via PGR, mainly PGR-A, expressing neurons in VMH (Gomez-Camarillo et al., 2011; Portillo et al., 2016; Flanagan-Cato et al., 2006; Sanathara et al., 2014; White et al., 2007; Acharya et al., 2015).

Pituitary

PGR is expressed in the pituitary gonadotropes (Sprangers et al., 1990; Turgeon et al., 1999; Turgeon and Waring, 2001). Gonadotrope PGR is essential for the GnRH stimulated and estrogen induced LH surge *in vivo* (Turgeon and Waring, 2001; Chappell et al., 1999; Attardi et al., 2007). *In vitro*, PGR mediates GnRH stimulation on the expression of the common α subunit (Chen et al., 2010), progesterone inhibition of the LH β subunit (Thackray et al., 2009) and activation of follicle stimulating hormone (FSH) β subunit expression (An et al., 2009; Thackray et al., 2006).

Ovary

In rodents, PGR expression is initiated in the pre-ovulatory granulosa cells and then rapidly induced by a LH surge, and dramatically decreases in luteinized granulosa cells (Sriraman et al., 2003; Park and Mayo, 1991; Shao et al., 2003; Kim et al., 2008). PGR is also detected in the peri-ovulatory follicles of humans, but persists in the active corpus luteum until regression (Chang et al., 2005; Robker et al., 2009). PGR deletion does not affect follicle development and luteinization in the mouse ovary (Robker et al., 2000). However, PGR is a key regulator of follicle rupture in both rodents and humans (Russell and Robker, 2007; Robker et al., 2009). Since PGR-A is more abundant in granulosa cells than PGR-B (Natraj and Richards, 1993; Toms et al., 2015), and mice lacking only PGR-A show severely reduced ovulation (Mulac-Jericevic et al., 2000), PGR-A is the predominant isoform in the murine ovary. PGR deletion does not impair luteinization in mouse ovary (Robker et al., 2000) but may play a role in the function of the corpus luteum of primate ovary (Stouffer, 2003).

Uterus

Similar to ESR, PGR is dynamically expressed in the uterus and regulates multiple events via paracrine factors [Reviewed in (Wetendorf and DeMayo, 2012; Bhurke et al., 2016)]. Interestingly, one of the major functions of PGR is to inhibit estrogen induced epithelial proliferation (Martin et al., 1973; Lydon et al., 1995; Tong and Pollard, 1999; Li et al., 2011). However, unlike ESR1 in which stromal ESR1 regulates epithelial cell proliferation, the inhibition of epithelial cell proliferation is initiated by PGR expressed in the epithelium (Nanjappa et al., 2015; Franco et al., 2012).

PGR is crucial for uterine functions during pregnancy. PGR ablation in the germline or specifically in the uterine epithelium of mouse shows disrupted embryo implantation and endometrial decidualization (Franco et al., 2012). A similar phenotype is observed in PGR-A knockout mice indicating that PGR-A is the major functional isoform in the mouse uterus (Mulac-Jericevic et al., 2000, 2003). In contrast, PGR-B has been found as functionally more potent for human endometrium decidualization than PGR-A (Bagchi et al., 2015). During pregnancy, PGR modulates physiological vascular permeability (Goddard et al., 2014), uterine fluid pH (Karim et al., 2016), decidua angiogenesis (Kim et al., 2013), and immune responses (Bhurke et al., 2016) of the uterus.

Not only is the expression of PGR critical for uterine function, but also the timing of PGR action and the ratio of PGR isoforms is critical for uterine function. Uterine epithelial PGR is high in the neonatal uterus even though its ligand progesterone is low. Uterine gland formation, adenogenesis, is disrupted by neonatal progesterone injections in the mouse through PGR signaling (Stewart et al., 2011; Cooke et al., 2012; Filant et al., 2012; Dhakal et al., 2015; Franco et al., 2012). During the receptive period of embryo attachment, epithelial PGR expression is decreased, extending PGR action in the uterine epithelium through this receptive phase disrupts pregnancy (Wetendorf et al., 2017). In humans, the ability of the uterus to support pregnancy and parturition is dependent upon the ratio of PGR-A and PGR-B. During pregnancy PGR-B is the dominant isoform maintaining pregnancy, in part, through its anti-inflammatory action. At the end of pregnancy, there is a shift in the ratio of PR-B to PGR-A. In this case PGR-A promotes parturition in part through its pro-inflammatory action (Nadeem et al., 2016; Ke et al., 2016; Tan et al., 2012; Patel et al., 2015).

Mammary gland

PGR is co-expressed with ESR1 in the mammary gland epithelium (Obr and Edwards, 2012). PGR is not essential for mammary gland development during embryonic and pubertal stages (Lydon et al., 1995). Despite this, a role of epithelial PGR in mammary duct growth during puberty has been suggested using pharmacological treatment and mammary epithelial transplant models (Shi et al., 2004; Briskin et al., 1998; Aupperlee et al., 2013; Atwood et al., 2000). During pregnancy, PGR is required for the extensive side-branching and alveologenesis via a paracrine mechanism (Satoh et al., 2007; Briskin et al., 1998; Lain et al., 2013). The fact that PGR-B not PGR-A knockout mice resemble the mammary defects of PGR knockout mice (Mulac-Jericevic et al., 2000, 2003) suggests the PGR-B is the major isoform that functions in the mammary gland.

Placenta

The presence of PGR in human fetal membranes is still controversial (Mesiano et al., 2011). PGR is detected in human decidua and declines after the onset of labor to maintain decidua before labor (Blanks and Brosens, 2012; Goldman et al., 2005). Meanwhile, functional withdrawal of PGR by shifting from PGR-B dominance to PGR-A dominance is also observed in the decidua (Zhuang et al., 2015; Goldman and Shalev, 2007). In human term placenta, PGR-A is found as the only form in the cytotrophoblast (Wang et al., 2014) while PGR-C is the major isoform in syncytiotrophoblast (Taylor et al., 2009). Both PGR-A and -B are expressed in several trophoblast cell lines, such as JEG3, BeWo cells, etc. (Yasuda et al., 2009; Zachariades et al., 2011; Lee et al., 2016). And progesterone can inhibit the invasion of BeWo cells (Jo et al., 2015; Chen et al., 2011).

AR

AR functions in male reproduction have been well defined, but the importance of AR in female reproduction has gradually drawn more attention. Actually, androgen deficiency and excess in females contribute to several pregnancy- and fertility-related disorders, such as polycystic ovarian syndrome (Apparao et al., 2002; Wang et al., 2015), endometriosis (Huhtinen et al., 2014), and recurrent pregnancy loss (Okon et al., 1998).

Hypothalamus, pituitary, ovary

AR is expressed in a variety of nuclei that are known to project to or regulate the hypothalamus in rodents and humans (Williamson and Viau, 2007; Mahfouz et al., 2016b; Dart et al., 2013; Fernandez-Guasti et al., 2000).

Deletion of AR in pituitary gonadotrope reduces the basal FSH levels and pre-ovulatory FSH and LH surge (Wu et al., 2014). Androgen, the cognate ligand of AR, stimulates FSH β expression in castrated rats (Wierman and Wang, 1990) and suppresses LH β expression in immortalized gonadotrope cells (Curtin et al., 2001; Jorgensen and Nilson, 2001). AR knockout mice exhibit hypothalamus–pituitary defects (Walters et al., 2009).

In the ovary, AR is expressed in granulosa cells, theca cells and the oocytes at almost all the estrous stages (Tetsuka et al., 1995; Horie et al., 1992). AR is involved in the follicle development and ovulation (Prizant et al., 2014; Walters et al., 2008) while global knockout of AR impairs follicle development and ovulation leading to subfertility (Walters et al., 2010).

Uterus

AR is found in both the stromal and epithelial compartments of the human endometrium with a cyclic expression pattern during the menstrual cycle (Ito et al., 2002; Marshall et al., 2011) and is still detected in the first trimester decidua (Milne et al., 2005). Similar expression patterns are found in the mouse uterus (Pelletier et al., 2004; Rothman et al., 2011; Xu et al., 2015). Previous studies suggest androgen function in uterine epithelium proliferation and gland formation (Simitsidellis et al., 2016), uterine receptivity during embryo implantation (Mokhtar et al., 2014b; Gibson et al., 2016), endometrial decidualization (Kajihara et al., 2012, 2014; Gibson et al., 2016), uterine ion secretion and water transport (Salleh et al., 2015; Mokhtar et al., 2014a), proliferation and apoptosis of uterine myometrium (Liu et al., 2013; Li et al., 2014). More interestingly, uterine gland epithelial-specific AR null mice have defective endometrial and myometrial proliferation suggesting that AR mediates the crosstalk between epithelium and other uterine compartments (Choi et al., 2015).

Mammary gland, placenta

AR is expressed in the luminal layer of mammary ducts and acini and in a subset of basal myoepithelial cells in pre-menopausal women and mammary epithelium in mice (Li et al., 2010; Tarulli et al., 2014). During puberty, androgens inhibit while AR antagonists stimulate the proliferation of mammary epithelium in humans and rodents (Tarulli et al., 2014; Peters et al., 2011).

In human placenta, AR is primarily present in the syncytiotrophoblasts and stromal cells, and dysregulation of AR may contribute to the placenta abnormality in preeclampsia pregnancy and gestational diabetes (Hsu et al., 2009; Sathishkumar et al., 2012; Uzelac et al., 2010).

GR

Due to the wide spread distribution of GR, glucocorticoid, the cognate ligand of GR, signaling has been found throughout the female reproductive system (Whirledge and Cidlowski, 2010, 2013b; Geraghty and Kaufer, 2015). On one hand, stress responses, mainly mediated through glucocorticoids, adversely affects female reproduction (Sapolsky et al., 2000). On the other hand, glucocorticoids are used to treat a variety of medical disorders in pregnant women (Roberts and Dalziel, 2006; Lunghi et al., 2010). Therefore, identifying the potential GR signaling pathways in female reproduction is urgent (Emin Turkyay Korgun et al., 2012).

Hypothalamus, pituitary, ovary

At central level, GR is expressed in the hippocampus, hypothalamus and amygdala etc., thus, GR may regulate GnRH neuron actions both directly and indirectly (Son et al., 2014; Gojska and Belsham, 2014; Takumi et al., 2012; Dondi et al., 2005; Nahar et al., 2016; Johnson et al., 2005; McEwen et al., 1986; Gore et al., 2006).

In the pituitary cells, glucocorticoids enhance FSH, but inhibit LH production (Suter and Schwartz, 1985; McGillivray et al., 2007; Breen et al., 2012), and synergize with GnRH to regulate the transcription of GnRH receptor (GnRHR) (Kotitschke et al., 2009).

In the ovaries, GR is present in the granulosa cells, theca cells, and surface epithelium cells (Tetsuka et al., 1999; Rae et al., 2004; Yuan et al., 2016; Myers et al., 2007). Glucocorticoids modulate the responsiveness of the ovary to FSH and LH (Michael et al., 1993; Hsueh and Erickson, 1978; Schoonmaker and Erickson, 1983), maintain the corpus luteum (Myers et al., 2007), and promote oocyte development (Jimena et al., 1992; Andersen, 2003; Yuan et al., 2016).

Uterus, mammary gland, placenta

GR is abundantly expressed in the rodent uterus and human endometrial cancer cell lines (Korgun et al., 2003; Thompson et al., 2002; Whirledge and Cidlowski, 2013a). Specific deletion of GR from the reproductive tract impairs embryo implantation and decidualization in mice (Whirledge et al., 2015). Glucocorticoids antagonize estrogen actions in the uterus probably via GR (Gunin et al., 2000, 2001, 2003; Rabin et al., 1990; Whirledge et al., 2013).

GR is ubiquitously expressed in human mammary glands (Lien et al., 2006; Buxant et al., 2010). GR null mammary glands when transplanted into wild-type mice show abnormal pubertal development (Kingsley-Kallesen et al., 2002). Although GR is essential for milk protein production *in vitro* (Stocklin et al., 1996), mammary epithelial deletion of GR during pregnancy and lactation disrupts the alveoli development, but not milk production in mice (Wintermantel et al., 2005). *In vitro* culture of mouse mammary epithelium also demonstrates the importance of glucocorticoids in acini formation (Murtagh et al., 2004).

GR is highly expressed in the placenta (Thompson et al., 2002; Clifton et al., 2016; Lee et al., 2005). Glucocorticoids reduce placenta weight (Ozmen et al., 2011; Mark et al., 2013; Baisden et al., 2007), probably by inhibiting proliferation (Zhang et al., 2016; Gennari-Moser et al., 2011) and inducing apoptosis (Chan et al., 2007; Baisden et al., 2007), and prevent angiogenesis in the placenta (Hewitt et al., 2006; Nugent et al., 2013).

MR

Studies concerning MR functions in female reproductive systems are limited. But MR has been found to be expressed throughout the female reproductive system.

At central level, MR is found in several distinct brain regions including the hypothalamus (de Kloet et al., 1993; Mahfouz et al., 2016b; Varga et al., 2013; Haque et al., 2015) and the pituitary (Moguilewsky and Raynaud, 1980; Krozowski and Funder, 1981) of rodents. In the rat ovary, MR immunostaining is most intense in the corpus luteum, light to moderate in oocytes and granulosa cells, and least intense in theca cells (Gomez-Sanchez et al., 2009). MR is also found in the ductal epithelial cells of human breast (Sasano et al., 1997). In the uterus, MR is found at the different stages of the menstrual cycle and the first-trimester of human pregnancy (McDonald et al., 2006). In the placenta, MR is moderately detected in human placenta, such as syncytiotrophoblasts, some cytotrophoblasts, and interstitial cells of the villous core (Hirasawa et al., 2000).

Some MR functions have been suggested in the uterus and placenta. MR deletion or repression alters lipid droplet biogenesis and retinoid metabolism in the decidualized primary human endometrial stromal cells (HESC) (Kuroda et al., 2013a, b). The activation of MR appears to be required for the proliferation of the trophoblasts, sodium transport of cytotrophoblast cells, and intracellular pH value of syncytiotrophoblast in the placenta (Gennari-Moser et al., 2011; Driver et al., 2003; Speake et al., 2010).

Future Directions

Previous studies on genetically modified mouse models and human cell lines demonstrate the critical roles and broad actions of SRs in the female reproductive system. However, with these studies come more questions that need answering. Further studies on the underlying mechanisms of the tissue-specific functions of multiple isoforms of EGR, PGR, and GR, etc., the reproductive roles of MR, AR, and GR, and the integrated analysis of SR activities with the recently developed high throughput bioinformatics are all needed. Furthermore, SRs, as well known nuclear receptors are good models to study the molecular mechanism of general transcription factors.

Nonclassical Steroid Receptors and Their Role in Regulating Female Reproduction

John J Peluso, University of Connecticut School of Medicine, Farmington, CT, United States

A Brief History of Nonclassical Steroid Receptors

The first edition of the *Encyclopedia of Reproduction* was published in 1998. In this massive text of 1297 pages, the idea that steroids could have rapid and/or membrane-initiated actions that were not dependent on the genomic action of classical nuclear steroid receptors was not even mentioned. Coincidentally in that same year, a group of about 100 scientists gathered in Mannheim, Germany to attend the First International Symposium on Rapid Responses to Steroids. Although rapid actions of steroids had been described, the cloning of classical nuclear steroid receptors in the late 1980s focused scientific research on the genomic mechanism through which steroids act. So much so that it prompted Norman and Wehling to state in their forward to the proceedings of this symposium that “nuclear receptors are believed by some researchers to account for the mechanism of action of all biological responses initiated by steroid hormones... and any unorthodox observations of apparent nongenomically mediated steroid effect [i.e., an action to rapid to be the result of differential gene expression] was either not believed by the researchers themselves or was in some instances, judged to be almost unpublishable due to the objections of the editors and/or the referees” (Norman and Wehling, 1999). It has taken nearly 20 years and 2489 publications since this symposium for the concept of nonclassical actions for steroids to be accepted (PubMed search terms: nonclassical or noncanonical and steroid; conducted June 20, 2017). However, the details as to the precise mechanisms that mediate these actions still remain to be elucidated. Consistent with the topics of Volume 2 of *Encyclopedia of Reproduction*, the focus of this article will be restricted to nonclassical actions of estrogen and progesterone as these steroids are the major steroids that regulate female reproduction. Finally, it is important to appreciate that this article is not intended to be a comprehensive review. Rather this article is intended to provide a general overview of how estrogen and progesterone mediate their actions through mechanisms that do not involve steroid receptor: DNA interaction and thereby regulate gene transcription. Unfortunately, this approach necessitates limiting the number of citations and omitting citations to many primary references.

Structural Features of Classical and Nonclassical Steroid Receptors

Estrogen Receptors

The first estrogen receptor cloned was the classical estrogen receptor α (ER α), which is encoded by the gene *Esr1*. ER α is a 66 kDa protein composed of six domains: A and B domains that contain transactivation site AF-1, a C domain which has the DNA binding domain (DBD), a D domain which includes the hinge region and the nuclear localization site (NLS), an E domain containing a ligand binding domain (LBD) and second transactivation site, AF-2 and the F domain comprising the c-terminal sequence. Exons 1–8 of *Esr1* encode these domains. There also exist splice variants of *Esr1*. Exons 2–8 encode ER α -46, while ER α -36 is encoded by Exons 2–6 and 9 of *Esr1*. *Esr2* encodes estrogen receptor β (ER β), which is a 56 kDa protein that possesses the same functional domains and shares significant sequence homology with ER α , especially in the C and E domains (Fig. 1A). Each of these estrogen receptor family members has a palmitoylation site that accounts in part for their ability to localize to cellular membranes (Soltysik and Czekaj, 2015).

In addition to estrogen receptors derived from either *Esr1* or *Esr2*, a G-protein coupled receptor was cloned in 2005. This G-protein coupled receptor was initially referred to a GPR30 but now is referred to as G-protein coupled estrogen receptor 1 (GPER1). GPER1 is a member of the rhodopsin-like receptor family and possesses seven transmembrane domains (Fig. 1B). GPER1 associates various G proteins that ultimately lead to either the stimulation or inhibition of different signal transduction pathways depending on its association with specific G proteins.

There are also other potential nonclassical mediators of estrogen's actions that have been proposed such as the putative Gq-mER (Micevych et al., 2015). These potential mediators of estrogen's actions are mainly associated with the regulatory functions of the hypothalamus. However, their molecular identities and functions have not been clearly demonstrated and therefore will not be discussed further.

Progesterone Receptors

The receptors that activate the nonclassical signaling for progesterone vary considerably. Basically, these receptors include members of (1) the classical nuclear progesterone receptor family (2) the progestin and adipoQ receptor family and (3) the membrane-associated progesterone receptor family. These receptor families are structurally unique as outlined below.

Classical nuclear progesterone receptors

The nuclear progesterone receptors have the five functional domains. There are two basic isoforms of the nuclear progesterone receptor referred to as progesterone receptor A (PR-A) and progesterone receptor B (PR-B). The PRs are encoded by the gene *Pgr*,

Fig. 1 The structural domains of estrogen receptor α (ER α), its splice variants (ER α -46 and ER α -36), estrogen receptor β , and G-protein coupled estrogen receptor 1 (GPER1). In panel (A), the localization of the transactivation site (AF-1), the DNA binding domain (DBD), the nuclear localization site (NLS), the ligand binding domain (LBD) and second transactivation site (AF-2) is shown in relationship to the color-coded domain. For these receptors the A/B domains are shown in *gray*, the C domain in *green*, the D domain in *white and black stripes*, E domain in *blue* and the F domain in *white and black checks*. In panel (B), the transmembrane domains of GPER1 are shown in *red*.

Fig. 2 The structural domains of progesterone receptors, PR-B, PR-A, and PR-M. In panel (A), the A/B domains are shown in *gray*, the C domain in *green*, the D domain in *white and black stripes*, E/F domains in *blue*. Note that in PR-M, the A, B, and C domains are replaced by a 16 amino acid sequence that allows for its mitochondrial localization. The transmembrane domains of PAQR7 are shown in *red* in panel (B). The area demarked by brackets and labeled as PAQR core also contains sequences similar to those of alkaline ceramidase. The transmembrane domain and heme binding domains of PGRMC1 and 2 are illustrated by the *red and green* areas, respectively in panel (C).

but because two different promoters are used PR-A lacks the first 164 N-terminal amino acids. Other than this, the two isoforms are identical (Fig. 2A). Interestingly, a small percentage of PR-B localizes to the plasma membrane and has the capacity of influence cellular function through membrane-initiated mechanisms (Kawprasertsri et al., 2016). The membrane-initiated action is largely mediated through a polyproline motif in the amino-terminal domain of PR-B. This polyproline motif allows PR-B to bind the SRC Homology 3 domain of Src kinase and leads to a rapid activation MAPK (mitogen-activated protein kinase) which is often referred to as ERK (extracellular signal regulated kinase) pathway (Kawprasertsri et al., 2016).

In addition there is another PR that has some structural similarities to the classic nuclear PRs. This PR is referred to as mitochondrial progesterone receptor, PR-M. PR-M is a truncated isoform of PR in which the initial 16 amino acids are encoded by a sequence located distal to the third intron followed by the sequence identical to exons 4–8 of *Pgr*. It is this N-terminal 16 amino acid sequence that is required for PR-M to localize to the outer mitochondrial membrane (Fig. 2A) (Price and Dai, 2015).

Progestin and adipoQ receptors

There are at least 11 members of the progestin and adipoQ receptor (PAQR) family. These receptors are similar to G-protein coupled receptors in that they have seven transmembrane domains. They also have similarities to the alkaline ceramidase family and may possess ceramidase activity (Moussatche and Lyons, 2012). These receptors localize to the plasma and cellular membrane where they regulate various signal transduction pathways. Although there are many members in this family, PAQR7, which is often referred to as membrane progesterone receptor α (mPR α), is more abundantly expressed in the ovary, uterus, and placenta thereby potentially contributing to progesterone-mediated responses that influence female reproduction. Its structure is illustrated in Fig. 2B. PAQR5 (a.k.a. mPR γ) is also expressed with its highest expression occurring mostly in the hypothalamus (Moussatche and Lyons, 2012).

Membrane-associated progesterone receptors

There are four members of the membrane-associated progesterone receptor (MAPR) family. These members include progesterone receptor membrane component 1, progesterone receptor membrane component 2, neudesin, and neuferricin. Each family member possesses a single transmembrane domain and the cytochrome *b5*-like heme/steroid binding domain. Moreover, these family members have numerous phosphorylation and sumoylation sites (Cahill, 2017). The first two family members cloned were progesterone receptor membrane component 1 (PGRMC1) and PGRMC2, respectively. Their structural features are illustrated in Fig. 2C. These two MAPR family members are expressed throughout the female reproductive axis and are the most extensively studied MAPR family members. As such, their mode of action will be discussed in subsequent sections of this article.

Nonclassical Steroid Receptors and Their Mechanisms of Action

Estrogen Receptors

Classical estrogen receptors and their splice variants

As previously indicated there are two classical nuclear estrogen receptors, ER α and ER β . In addition, there are several splice variations of *Esr1*. The two most frequently detected splice variants are ER α -46 and ER α -36. All four of these ERs have been detected at the plasma membrane and can potentially activate various signal transduction pathways. Precise details as to how these ER receptors mediate their membrane-initiated actions are still being investigated. However, each of these receptors contains palmitoylation sites and when palmitoylated bind to caveolin-1, which facilitates their localization to the plasma membrane. Once at the plasma membrane the ERs can interact with various growth factor receptors, G-proteins, and kinases (Fig. 3). Through these interactions, exposure to estrogen can result in the activation of different signal transduction pathway (e.g., PI3 Kinase, ERK, AKT, and Protein Kinase A) (Arnal et al., 2017). These actions have most predominately been shown for ER α and its splice variant ER α -36. Also Levin's group has shown membrane-initiated actions of ERs promote the production of nitrous oxide. It is important then to appreciate that each of these ER-regulated downstream signal transduction cascades could play essential roles in regulating the function of specific organs and tissues that comprise the female reproductive system. Whether nonclassical actions of estrogen are mediated via membrane-initiated actions of ERs is dependent on the expression profile of the various ERs, their palmitoylation status, and the level of estrogen associated with specific physiological conditions.

G-protein coupled estrogen receptor 1

Most studies indicate that ligand activation of GPER1 stimulates the ERK signaling pathway. An interesting model to explain how ligand activation of GPER1 increases ERK activity has been proposed by Gonzalez de Valdivia et al. (2017). In this model GPER1 is

Fig. 3 Membrane-initiated mechanism regulated by classical estrogen receptors. The various components are identified within the figure.

bound to a complex composed of membrane-associated guanylate kinase, A-kinase anchor protein 5 and the regulatory II component of protein kinase A. This protein complex ultimately constitutively inhibits cAMP production. Exposure to the GPER1 agonist, G-1, disrupts this complex and thereby removes the inhibition on cAMP production and increases the coupling of Gi/o proteins to GPER1, which results in greater stimulation of the ERK signaling pathway. GPER1 is also thought to modulate intracellular free calcium levels. While this is an interesting model of GPER1's actions, it is mainly based on *in vitro* studies, often after forced expression of GPER1. Therefore, caution must be exercised regarding the GPER1's capacity to regulate these signaling pathways in such a way as to have a major influence on female reproductive function.

Progesterone Receptors

Classical progesterone receptors

The N-terminal region of PR-B possesses a polyproline domain, which binds to the Src homology domain 3 (SH3) of Src kinase. Moreover, this domain is required for ligand activation of PR-B to stimulate Src and subsequently ERK activity (Fig. 4). This is evidenced by the fact that mutating the polyproline domain eliminates the capacity of PR-B to stimulate these kinases. Interestingly, elevated levels of PR-B attenuate the function of the epidermal growth factor receptor, indicating that PR-B competes with this growth factor receptor for the binding to the SH3 domain of Src (Kawprasertsri et al., 2016). The ability of PR-B to localize to the plasma membrane may be facilitated by its undergoing palmitoylation, but the functional evidence for this is not as strong as that involving ER α .

PR-M shares structural similarities to PR-A and PR-B. PR-M appears to be a truncated form of PR with its major characteristic being that it localizes to the outer mitochondria membrane (Fig. 4). In addition genetic enhancement and ablation experiments reveal that PR-M mediates progesterone's ability to increase cellular metabolism *in vitro*. It has been suggested that PR-M may account in part for progesterone's well-known ability to increase basal body temperature. Since progesterone is cell permeable, it is likely that PR-M influences cellular energy production to meet the energy demands of women, especially during pregnancy (Price and Dai, 2015).

Progesterone and adipoQ receptor family

A detailed discussion of the potential signal transduction pathways that could be activated by each of the 11 members of this family is not within the scope of this article. Since PAQR7 expressed throughout the female reproductive axis, the effect of progesterone that are mediated via PAQR7 will be presented. One of the more defined pathways involves that activation of both the PI3 kinase/AKT and the ERK pathways, while inhibiting cAMP production (Fig. 4). Other G-protein coupled modes of PAQR7's action have been proposed and are reviewed in more detail by Valadez-Cosmes et al. (2016).

In addition to the G-protein coupled mechanisms, another signaling mechanism has been proposed based on the observation that PAQR family members share sequences consistent with alkaline ceramidases. It has been suggested that progesterone could stimulate PAQR-based alkaline ceramidase activity, which would convert ceramides into sphingolipids. Further metabolism of sphingolipid results in sphingosine-1-phosphate, which in turn could activate one of five different G-protein coupled sphingosine-1-phosphate receptors. This mode of action could lead to modulation of various G-protein dependent signaling pathway (Moussatche and Lyons, 2012).

Fig. 4 Membrane-initiated mechanism regulated by the various progesterone receptors. The different components of each pathway are identified within the figure. Components connected by *black arrows* are stimulated while components in *gray* and connected by *gray arrows* are inhibited.

Membrane-associated progesterone receptor component family

Most of the studies related to mechanism through which PGRMC1 and PGRMC2 regulate female reproductive function have been largely restricted to cell lines derived from the ovary. These studies have implicated (1) the activation of protein kinase G, (2) the inhibition of ERK, and (3) the suppression T-cell-specific transcription factor/lymphoid enhancer factor activity as components of the progesterone-PGRMC1 signaling pathway that preserves cell viability (Peluso and Pru, 2014). Progesterone's ability to suppress the entry of granulosa cells into the cell cycle is mediated by PGRMC1 and PGRMC2 as treatment with siRNA directed against either MAPR family member results in an inappropriate entry into the cell cycle. This frequently results in the cells undergoing apoptosis. How progesterone acts through PGRMC1 and PGRMC2 to restrict entry into the cell cycle is not known. What is known is that PGRMC1 interacts with PGRMC2 and both MAPR family members bind GTPase-activating protein-binding protein 2 (G3BP2). G3BP2 binds nuclear factor kappa light polypeptide gene enhancer in B-cells inhibitor, which is commonly referred to as I κ B α . I κ B α binds nuclear factor κ B (NF- κ B), thereby retaining the I κ B α :NF- κ B complex within the cytoplasm (Fig. 4). Based on this, it is proposed that (1) PGRMC1 and PGRMC2 restrict entry into the cell cycle by anchoring NF- κ B to the cytoplasm and (2) progesterone intensifies these interactions making it more difficult for NF- κ B to translocate to the nucleus and up regulate genes that initiate entry into the cell cycle (Peluso et al., 2014). These observations provide the rationale for further investigation of this potential signal transduction cascade.

PGRMC1 could also affect epidermal growth factor signaling. It could do so by facilitating the plasma membrane localization of the epidermal growth factor receptor to the plasma membrane (Fig. 4) (Kabe et al., 2016). Similarly, PGRMC1 directs the ER β to the membrane (Thomas et al., 2014). In this manner PGRMC1 has the capacity to influence numerous signal transduction pathways.

Function of the Nonclassical Steroid Receptors in the Female Reproductive System

Estrogen Receptors

Classical estrogen receptors and their splice variants

The classic estrogen receptors, ER α and ER β , are expressed throughout the female reproductive axis and play essential roles in female reproduction. Functional evidence of their roles in reproduction is demonstrated by the observations that various knockout and knockin mice are infertile (Hewitt et al., 2016). Females from the different ER α mouse lines are all infertile, due to alterations ovarian and uterine function, while impaired fertility in female ER β knockout mice is largely due to the failure of the ovary to respond to gonadotropins (Hewitt et al., 2016).

Interestingly, both ER α and ER β are involved in regulating gonadotropin releasing hormone (GnRH) and in turn gonadotropin secretion (Radovick et al., 2012). The ER α is expressed by the gonadotropes within the pituitary and the kisspeptin expressing neurons of the anteroventral periventricular nucleus and arcuate nucleus within the hypothalamus. These kisspeptin expressing neurons activate GnRH neurons, which express ER β thereby providing multiple sites for estrogen's action. Moreover, the mechanism through which estrogen mediates its effects most likely includes both classical and nonclassical actions. For example, Yan et al. have shown that estrogen-dependent gene expression in the arcuate nucleus of the hypothalamus is not dependent on ER α interactions with the estrogen response element (ERE) within the promoters of specific genes. Rather it appears that ERE-independent genomic actions are due to ER α "tethering" to other DNA-associated transcription factors. This nonclassical mode of action could be important in regulating gonadotropin secretion and thereby female reproduction (Yang et al., 2017). As previously discussed, ERs can localize to the plasma membrane and in turn activate ERK pathway through an interaction with growth factors receptors. Thus, ER α and ER β likely have both classical and nonclassical modes of action, which mediate estrogen's effects at the level of both the hypothalamus and pituitary.

The potential roles for ERs derived from *Esr1* (i.e., ER α -46 and ER α -36) in regulating female fertility are difficult to discern. For example, ER α -46 localizes to cytoplasmic membrane and is expressed in numerous cell types including vascular endothelial cells and many cancers. It is also expressed in the ovary and uterus but at levels much lower than in nonreproductive tissue such as liver (Irsik et al., 2013). While its role in regulating reproduction has not been characterized, the most plausible site of action is the vascular endothelial cells within organs of the reproductive axis (Arnal et al., 2017). Unfortunately genetically modified mice are not available to examine the specific actions of ER α -36, therefore definitive conclusion regarding ER α -36's role in female reproductive function cannot be drawn at this time.

G-protein coupled estrogen receptor 1

In most mammalian species that have been examined, GPER1 is expressed in the hypothalamus specifically in the neurons expressing gonadotropin-releasing hormone (Zimmerman et al., 2016). It is also present in ovary and uterus but its level of expression is considerably less than that of ER α (Zimmerman et al., 2016). This expression pattern is suggestive of a role for GPER1 in female reproduction, but this is controversial as several different knockout mouse lines are fertile (Otto et al., 2009; Langer et al., 2010; Zimmerman et al., 2016). Based on these findings, it does not appear that GPER1 has a significant role in the regulation mammalian female reproductive function. However, some caution should be exercised in drawing this conclusion, because most fertility trials were conducted over a short period of time and GPER1 function may only be revealed as the female mice age. Support for age-related effects of GPER1 is provided by the findings of Wang et al. (2008) who showed that GPER1 is expressed in the somatic cells of the neonatal hamster ovary and GPER1 siRNA treatment suppressed estrogen-induced formation of primordial follicles. It is possible then that the GPER1 knockout mice will have fewer primordial follicles and therefore have a shorter reproductive lifespan, which would not have been detected in the previous 2-month fertility trials. This possibility merits further investigation.

It is also possible that GPER1 plays a subtle role in female reproduction. For example, female GPER1 knockout mice show estrous cycle dependent alterations in serum corticosterone levels and stress coping abilities (Kastenberger and Schwarzer, 2014). Thus, GPER1 could be involved in the regulation of age-related changes in blood pressure, vascular remodeling, heart failure (Zimmerman et al., 2016), and metabolic disorders including estrogen-regulated anorectic affects (Kwon et al., 2014).

Progesterone Receptors

Classical progesterone receptors and their splice variant

It is indisputable that the PR-A and PR-B are important regulators of female fertility given that their ablation results infertile mice. This is not surprising since these receptors are present through the reproductive axis. The ablation of PRs adversely alters the ability of progesterone to regulate uterine function, as well as ovulation and the regulation of GnRH-induced luteinizing hormone secretion (Radovick et al., 2012). Although these PR-dependent functions have a profound effect on female reproductive function, it is not entirely clear whether the classical PRs mediate their affects solely through a direct interaction with the promoters of specific genes or whether any of their actions are initiated at the plasma membrane.

Progesterone and adiponectin receptor family

As with the PRs, the PAQR family members are expressed in the hypothalamic nuclei (Petersen et al., 2013), the mammalian ovary, most notably within the corpora lutea (Peluso and Pru, 2014) and in the uterus (Peluso and Pru, 2014). Unfortunately, PAQR knockout mice have not been generated so the role that PAQR family members play in regulating female fertility remains to be conclusively demonstrated.

One potential mechanism by which PAQR7 could influence progesterone's actions in female reproductive system was revealed by in vitro studies involving PGR negative breast cancer cells lines and PGR negative spontaneously immortalized granulosa cells. In this study, forced expression of *Pgrmc1* increased the amount of PAQR7 that localized to the plasma membrane with a corresponding increase in the capacity of the cells to bind progesterone and activate G proteins. Conversely, forced expression of *Paqr7* increased (1) the amount of PAQR7 and PGRMC1 that localized to the plasma membrane, (2) the interaction between PAQR7 and PGRMC1, and (3) progesterone's ability to inhibit apoptosis. Importantly, progesterone's antiapoptotic actions were attenuated by treatment with *Paqr7* siRNA (Thomas et al., 2014). Therefore, this study suggests that a functional interaction between these two nonclassical progesterone receptors exists, but this remains to be demonstrated in vivo.

Membrane-associated progesterone receptor component family

To investigate the role that PGRMC1 and PGRMC2 play in regulating female fertility, various conditional knockout mouse lines have been generated (McCallum et al., 2016; Clark et al., 2017). The effect of depleting these MAPRs was a decline in fertility as judged by a decrease in litter size, with the decline in litter size generally increasing maternal age. The most dramatic decline in litter size was observed in mice in which the *Pgr-cre* driver was used to ablate *Pgrmc1* and *Pgrmc2* (Clark et al., 2017). In this mouse line, the conditional *Pgrmc1/2* knockout mice ovulated and became pregnant but the birth of pups was rarely observed after 6 months of age compare to controls whose fertility was not affected at 6 months of age. The major cause of the reproductive wastage was associated with implantation site reabsorption due to faulty decidualization. A much more limited decline in female fertility was observed when an antimüllerian hormone receptor type 2-*cre* driver was used to ablate *Pgrmc1* with reproductive loss associated with uterine defects, although some impairment of follicle growth was also observed (Peluso and Pru, 2014). Finally, a role for progesterone-PGRMC1 signaling in regulating the formation of primordial ovarian follicles has been proposed (Guo et al., 2016). It is likely that disrupting PGRMC1 expression during primordial follicle formation shortens the reproductive lifespan, since lower levels of PGRMC1 are observed in some women who have undergone the premature loss of the primordial follicle population and premature menopause (i.e., premature ovarian insufficiency) (Mansouri et al., 2008).

Summary and Future Directions

In this article each of the nonclassical estrogen and progesterone receptors was presented as a separate entity. However, the responses to estrogen and/or progesterone are dictated by both the level of expression of each classical and nonclassical steroid receptor as well as the steroid levels to which the cell is exposed. One thing that is striking about the membrane-initiated actions of both estrogen and progesterone is that they often regulate the same downstream signal transduction pathways, most notably the PI3K/AKT and the ERK pathways. The physiological rationale for this commonality between estrogen and progesterone actions is unknown. It may actually reflect our tendency to monitor a few well-established markers of biological function and our failure to examine responses in a more global sense. In this light the use of more discovery approaches such as kinase activity screening might provide a more complete picture of the components of the membrane-initiated mode of action.

Another perplexing issue that limits our understanding of how estrogen and progesterone modulate biological responses is that the nonclassical steroid actions, which localize to the plasma membrane, often lead to the transcription of specific genes. Thus, differentiating these genomic responses from those triggered by direct nuclear steroid receptor: DNA interaction is difficult. Resolving this issue will be necessary in order to truly understand the complete and complex mechanism through which each steroid acts.

What is essential then is that these variables be considered in both designing and, more importantly, interpreting the outcomes of experiments. This is especially true for studies involving genetically modified mice as depleting one gene may either enhance the

expression of genes and/or induce redundant signal pathways to compensate for the loss of the targeted gene. These realities should be incorporated into our thinking in order to deepen our understanding of how a specific cell will respond to estrogen and/or progesterone under different physiological conditions.

In conclusion over the last 20 years, the concept of nonclassical membrane-initiated actions of both estrogen and progesterone has been established and is no longer thought of as an experimental artifact. Importantly, the receptors that mediate these steroid actions have been identified and with their identification genetic approaches and in vitro systems used to demonstrate that these receptors account for specific aspects of estrogen and progesterone signaling. More recently the generation of genetically modified mice has been used to conclusively illustrate the physiological relevance of some of these nonclassical steroid receptors. The major void now is in defining components of the signal transduction pathways that are activated in response to the membrane-initiated actions of each steroid and to different these components from those associated the direct nuclear steroid receptor: DNA interactions. This is not a trivial task and will likely require the application of discovery analytical tools such as RNAseq and proteomic analysis coupled with intensive bioinformatic analyses. This approach alone however will not be sufficient in that genetic approaches will be required to dissect each newly proposed component of these putative pathways. Hopefully over the course of the next 20 years, these details of steroid signaling will be elucidated.

Ovarian Production of Estradiol: The Two-Cell, Two-Gonadotropin Model

Joanne E Fortune, Cornell University, Ithaca, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Female reproductive cycles are regulated by endocrine signals between the hypothalamus-pituitary and the ovary. Mammalian ovaries synthesize all three classes of sex steroid hormones: progestins, androgens, and estrogens. The estrogenic steroid estradiol is the most important endocrine signal produced by the ovary during the follicular phase of female reproductive cycles. A consideration of circulating levels of reproductive hormones during estrous and menstrual cycles of mammalian species reveals a consistent dramatic increase in circulating estradiol. The rise in estradiol peaks just prior to and induces the preovulatory surge of gonadotropic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), that triggers ovulation. The developing preovulatory follicle(s) is responsible for the large and rapid increase in circulating estradiol prior to the LH/FSH surge. During the follicular phase, circulating estradiol also has a number of other targets in addition to the hypothalamus-anterior pituitary. It promotes changes in the reproductive tract (vagina, cervix, uterus, and oviducts) and the mammary glands that prepare the female for gamete transport and fertilization and for potential pregnancy and lactation. In addition, estradiol exerts paracrine and autocrine effects within developing preovulatory follicles that promote their development.

Despite the central importance of follicular estradiol production to female reproduction, the cellular site and regulation of estradiol synthesis within developing preovulatory follicles were difficult to determine. One reason was the lack of sufficiently purified gonadotropins before the 1970's. The gonadotropic hormones, LH and FSH, synthesized and secreted by the anterior pituitary gland, are glycoproteins with unique beta subunits, but identical alpha subunits. This structural similarity made it difficult to obtain completely (or even mostly) pure preparations of either hormone by isolating them from pituitary glands. The availability of purer preparations of LH and FSH, together with the development of methods for separating and culturing the two follicular endocrine cell types, theca and granulosa cells, were advances important for studying follicular steroid production. In addition, the development of radioimmunoassays (RIAs) provided much more sensitive methods for measuring hormones and was critical for accurate measurement of the small amounts of steroids secreted by follicular cells *in vitro*. These advances allowed the two-cell, two-gonadotropin hypothesis of follicular estradiol production to be tested more directly than in previous experiments. There is now experimental evidence that the two-cell, two-gonadotropin model describes the regulation of estradiol biosynthesis by preovulatory follicles in a number of mammalian species.

Pathways of Steroidogenesis

As mentioned above, sex steroids are members of one of three general classes: progestins, androgens, and estrogens. The steroids within each class share structural and functional similarities. Cholesterol is the precursor of all steroid hormones (Fig. 1). Within the biosynthetic pathway of sex steroids, cholesterol is converted to the progestin pregnenolone via the P450 side-chain cleavage enzyme (CYP11A1). Progestins serve as precursors for androgenic steroids and androgens in turn are precursors for estrogen synthesis (Fig. 1). Thus, steroid hormones play roles both as precursors for the synthesis of other steroids and as endocrine factors that exert actions by binding to receptors. Both ovaries and testes synthesize all three classes of sex steroids, but the relative amounts produced and the steroids that are used for endocrine signaling to other parts of the body differ in males and females. In mammalian females, estradiol is the dominant circulating sex steroid during the follicular phase of the reproductive cycle, but it is obvious from Fig. 1 that synthesis of progestins and androgens is necessary for the production of estradiol. In contrast, progesterone made by

Fig. 1 The pathway of ovarian sex steroid biosynthesis. Enzymes that catalyze each conversion are indicated in red. Androgens can be synthesized via the delta 4 ($\Delta 4$, blue arrow) and/or delta 5 ($\Delta 5$, yellow arrow) pathways.

the corpus luteum is the dominant circulating sex steroid during the luteal phase of the cycle, although estradiol is also elevated in some species (e.g., rodents, primates).
